LINENTHAL, H., M.D.
LOVETT, ROBERT W., M.D.
LUND, F. B., M.D.
MARION, HORACE E., M.D.
MAYO, WILLIAM J., A.M., M.D.
MAYS, THOMAS G., A.M., M.D.
McDONALD, WILLIAM, JR., M.D.
MILLER, A. ERSKINE, M.D.
MONTGOMERY, F. H., M.D.
MORSE, JOHN LOVETT, A.M., M.D.
MUMFORD, JAMES G., M.D.
MUNRO, JOHN C., M.D.
MURPHY, FRED T., M.D.
MUSSER, JOHN H., M.D.
O'CONOR, JOHN, M.A., M.D.

O'NEIL, RICHARD FROTHINGHAM, M.D.
OTIS, EDWARD O., M.D.
PAGE, CALVIN G., M.D.
PALMER, SARAH ELLEN, M.D.
PERKINS, JAY, M.D.
PORTER, CHARLES ALLEN, M.D.
PORTER, P. BRYNBERG, M.D.
POST, ABNER, M.D.
POWERS, CHARLES A., M.D.
PRATT, JOSEPH H., A.M., M.D.
PRINCE, MORTON, M.D.
PUTNAM, J. J., M.D.
QUACKENBOSS, ALEX., A.M., M.D.
QUINBY, WILLIAM CARTER, M.D.
REYNOLDS, EDWARD, M.D.
RICHARDSON, MAURICE H., M.D.
ROBINSON, BEVERLEY, M.D.
ROBINSON, BYRON, B.S., M.D.
ROTCH, T. M., M.D.
SCUDDER, CHARLES L., M.D.
SEARS, GEORGE G., M.D.
SHATTUCK, FREDERICK C., M.D.
SHATTUCK, GEORGE B., A.M., M.D.
SIDIS, BORIS, A.M., PH.D.
SMITH, JAMES A., M.D.
STEVENS, HENRY B., M.D.
STEWART, H. JOHN, M.D.
STONE, ARTHUR K., M.D.
STONE, J. S., M.D.
STORER, MALCOLM, M.D.
SWIFT, WILLIAM N., M.D.
SYLVESTER, CHARLES P., M.D.
TAYLOR, E. W., M.D.
TENNEY, BENJAMIN, M.D.
THOMSON, W. H., M.D., LL.D.
THORNDIKE, PAUL, M.D.
TOWNSEND, CHARLES W., M.D.
TWOMBLY, EDWARD L., M.D.
VICKERY, H. F., M.D.
WADSWORTH, RICHARD G., M.D.
WALTON, G. L., M.D.
WARREN, J. COLLINS, M.D.
WATSON, F. S., M.D.
WHITE, LEON E., M.D.
WHITESIDE, G. S., M.D.
WHITNEY, WILLIAM F., M.D.
WILLIAMS, FRANCIS H., M.D.
WITHINGTON, CHARLES F., M.D.
WORCESTER, A., M.D.
WOSE, A. M., M.D.
YOUNG, ERNEST BOYEN, M.D.

INDEX TO VOLUME CL.

AUTHORS.

Abbott, Samuel W. Progress in public hygiene, 376, 404.
Aldrich, Charles J. The bicycle as a therapeutic agent, 107.
Atwood, Charles A. A case of traumatic cerebral hemorrhage, 325; a case of appendicitis with general peritonitis, 347.

Baginsky, Adolf. Typhoid fever in children, 10.
Balch, Franklin G. Some cases of intussusception, 39; report of cases of decapsulation of the kidneys, 90; use of cystoscope in determining what operation is advisable in prostatic hypertrophy, 457.
Baldwin, H. C. A case of hysteria, 185.
Bartol, J. W. Report on thoracic disease, 297.
Benedict, Francis Gano. Scientific aspects of moderate drinking, 174.
Bigge, Hermann M. Preventive medicine: its achievements, scope and possibilities, 668.
Binney, Horace. Claudius' iodized catgut, 504.
Birge, William S. A new treatment for morphine addiction, 401.
Bishop, Louis Faugeres. Concerning danger of infection in attendants of tubercular patients, 507.
Blake, J. B. Nephrocapsulectomy, 539.
Blodgett, Albert N. Imposter, 167.
Bolles, W. P. Amputation at hip joint, 537.
Bowditch, Vincent Y. Arrested tuberculosis: subsequent histories of cases treated at the Sharon sanatorium, 308.
Bowen, John T. Report on dermatology, 484; clinical report from the ward for skin diseases at the Massachusetts General Hospital, 564.
Bradley, Charles H. An account of the work, including obstetrical technique, at the Lying-In Hospital of the City of New York, 299.
Brewster, G. W. W. A case of ruptured spleen; operation and recovery, 211.
Brown, Francis H. The medical register for New England, 55.
Buckingham, E. M. Gastric ulcer, 538.
Bullard, William N. Contribution to the etiology of idiocy and imbecility, 471.
Burley, Benjamin T. Bilateral facial atrophy, with report of a case and its treatment by subcutaneous injection of paraffin, 391.
Burrage, W. L. Recent progress in gynecology, 326, 348.
Burrell, Herbert L., and Cushing, Hayward W. The progress of surgery, 511, 541, 566, 589.

Cabot, Arthur Tracy. A brief résumé of present status of treatment of enlarged prostate, 458.
Cabot, Hugh. Results of operations upon prostate, Massachusetts General Hospital, from Jan. 1, 1892, to July 1, 1893, 456.
Cabot, Richard C. Alcohol and alcoholism, 281; ring bodies in anemic blood, additional forms, 381.
Chute, Arthur L. Some clinical observations on care of septic wounds, 423; gross pathology and mechanism of prostatic obstruction, 451; a sigmoid band of unusual origin. Operation. Relief, 476.
Clark, F. C. Action of resorcin, 483.
Codman, E. A. Some points of diagnosis and treatment of certain neglected minor surgical lesions, 371; report of a case of bone cyst of a digital phalanx, 211; a résumé of the results of Dr. F. B. Harrington's service, Massachusetts General Hospital, from June 1 to October 1, 1902, as seen in the following June or later, 618.
Coolidge, A., Jr. Recent progress in laryngology, 186, 212; deviation of nasal septum, 498.
Courtney, J. W. Dr. Watson and Mr. Holmes; or the worm that turned, 553.
Craig, Daniel H. Hystero-neuroses and their relation to the physical examination of all women patients, 497.
Crandon, L. R. G. Surgical anatomy of prostate, 450.
Cushing, H. W. Bullet wounds of the head, chest and abdomen, 538.

Dana, Charles L. The partial passing of neurasthenia, 339.
Denny, Francis P. Disinfection of the clinical thermometer, 585.
Dock, George. Prognosis, its theory and practice, 605.

Edebohls, George M. A second case of puerperal eclampsia successfully treated by renal decapsulation, 586.
Edes, Robert T. The relation of some special causes to the development of neurasthenia, 227.
Ehrlich, Paul. Herter lectures, 443; mutual relations between toxin and antitoxin, 443; physical chemistry *v.* biology in doctrine of immunity, 445; cytotoxins and cytotoxic immunity, 448.
Emerson, Francis P. Local conditions in the respiratory tract modified by general functional or organic disease, 508.
Emley, S. O. Carcinoma basocellulare. A group of superficial gland-like tumors of the skin, of relatively slight malignancy, including rodent ulcer, 611.
Ernst, Harold C. Some fermentations in medical education, 661.

Faulkner, William E. Blood-pressure observations in surgical cases, at the Boston City Hospital, 255.

Garceau, Edgar. Removal of calculus in ureter by a new method, 426.
Gilman, Warren R. The use of obstetric forceps, 189.
Goldthwait, Joel E. Slipping or recurrent dislocation of the patella. With the report of eleven cases, 169; infectious arthritis, 363.
Green, Charles M. A case of pregnancy in a uterus bicornis unicollis, 620.
Greenough, Robert B. Enterostomy in peritonitis, 525.
Gulick, Luther Halsey. The bicycle as a therapeutic agent, 40.

Hamilton, Annie Lee. A case of labor in an epileptic, 680.
Hammond, Philip. Progress in otology, 706.
Harrington, Charles. Mercuric cyanide as a surgical disinfectant, 43; sulphurous acid and its salts as food preservatives, as aids to fraud, and as possible causes of lesions of the kidneys, 555.
Harrington, F. B. Perineal prostatectomy, 482.
Harrington, Thomas F. Differential diagnosis of rheumatism and arthrites, 85.
Harvey, William W. A case of carbolic acid poisoning, 649.
Higgins, Frank A. Report on obstetrics, 242, 272; vaginal section in the treatment of extra-uterine pregnancy, 561.
Holyoke, Frank. An attempted suicide by illuminating gas, 324.
Howard, William Lee. Morphine and menstruation, 167.
Hubbard, Joshua C. Decapsulation of the kidneys, 93.

Jackson, Henry. Tubercular meningitis in adults, 501.
Jackson, James Marsh. Thyroidectomy for exophthalmic goiter; obstruction of the superior vena cava, 185.

Kahn, I. Stanley. Two simple formulæ for use in the artificial feeding of infants, 296.
Keefe, John W. A new needle holder, 297.
Kilburn, Henry W. Eye-strain considered as a factor in production of lateral curvature of spine (preliminary communication), 318.
Knapp, P. C. Tremor of right arm. Loss of muscular sense and ataxia, 539.

Larrabee, R. C. Arrest of development, probably resulting from congenital syphilis, 540; myxedema, 540.
Lisenthal, H., Sidis, Boris, and Prince, Morton. A contribution to the pathology of hysteria based upon an experimental study of a case of hemianesthesia with clonic convulsive attacks simulating Jacksonian epilepsy, 674.
Lord, Frederick K. "Arrested tuberculosis." Should unproved cases be thus recorded? 274.
Lovett, Robert W. Forcible correction in lateral curvature of the spine. Fourth paper, 283.
Lund, F. B. Prostatectomy; spinal anesthesia, 460; cholecystectomy, 539; laminectomy for fractured spine, 540.

Marion, Horace E. A many-phased case of chorea, 397.
Mayo, William J. The association of surgical lesions in the upper abdomen, 641.
Mays, Thomas G. Human slavery as a prevention of pulmonary consumption, 647.
Minot, Charles S. The embryological collection of the Harvard Medical School, 107.
Montgomery, F. H. German measles, 510.
Morse, John Lovett. A case of traumatic hemopericardium, 240.
Mumford, James G. Finney's operation for pyloric stenosis: sudden death in status lymphaticus, 482.
Munro, John C. Report of cases of trephining for epilepsy, 109.
Murphy, Fred T. Experiments with the McGraw elastic ligature, 81; blood-pressure observations in surgical cases, at the Massachusetts General Hospital, 264.
Musser, John H. Some aspects of medical education, 633.

O'Conor, John. Radical cure of inguinal hernia, 374.
O'Neil, Richard Frothingham. A case of stone in the bladder in a boy of fifteen, 678.
Otis, Edward O. The significance of the tuberculosis crusade, and its future, 694.

Palmer, Sarah Ellen. A case of tuberculous contagion, 588.
Perkins, Jay. The relation of the burn to the bullet hole as evidence of homicide *vs.* suicide: report of the Nagle case, 616.
Porter, Charles Allen, and Quinby, William Carter. A case of ovarian tumor with twisted pedicle. Three reductions without operation. Operation; recovery, 375.
Post, Abner. Septicemia from the Bacillus mucosus capsulatus, 536.
Powers, Charles A. Cancer of the rectum; combined abdominal and perineal operation, 63.
Pratt, Joseph H. Hydrotherapeutic prescriptions, 288; report on pathology, 497.
Prince, Morton, Sidis, Boris, and Lisenthal, H. A contribution to the pathology of hysteria based upon an experimental study of a case of hemianesthesia with clonic convulsive attacks simulating Jacksonian epilepsy, 674.
Putnam, J. J. A case of Huntington's chorea; its social aspects, 399; two cases of crural monoplegia of traumatic origin, 481.

Quackenboss, Alex. Ligation of lachrymal canal to prevent infection following cataract extraction, 347.

Reynolds, Edward. Decapsulation of the kidneys, 122.
Richardson, Maurice H. Intermittent hydronephrosis—uterine fibroid, 37; remarks upon cholecystectomy and cholecystostomy, with special reference to their comparative safety and efficiency in the treatment of biliary affections, 139.
Robinson, Beverley. Introductory lecture at University Bellevue Hospital Medical College, 417; the physiology of the ureter, 698.
Robinson, Byron. The physiology of the ureter, 698.
Rotch, T. M., and Morse, J. L. Report on pediatrics, 43, 66.

Scudder, Charles L. Cholecystostomy and cholecystectomy. A

study of a certain series of operations, 145; a study of certain cases of sarcoma of the long bones from the Massachusetts General Hospital clinic, 579.
Sears, George G. The prognosis of idiopathic pleurisy, 209.
Shattuck, Frederick C. The general management of diabetes, 199; anomalies of thyroid secretion, 689.
Sidis, Boris, Prince, Morton, and Linenthal, H. A contribution to the pathology of hysteria based upon an experimental study of a case of hemianesthesia with clonic convulsive attacks simulating Jacksonian epilepsy, 674.
Stevens, Henry B. Three cases of hemorrhagic disease of the newborn, 565.
Stewart, H. John. The Finsen light cure, 16.
Stone, Arthur K. Cardiac displacement, 29.
Stone, James S. Blood-pressure observations in surgical cases, at the Boston Children's Hospital, 262.
Storer, Malcolm. On some questions relative to extra-uterine pregnancy, with especial reference to tubal abortion, 5.
Swift, William N. Cesarean section for placenta previa in a primipara, 65.
Sylvester, Charles P. Typhoid fever in infancy, with report of case complicated with meningitis terminating in recovery, 321.

Tenney, Benjamin. Some conclusions based on a study of one hundred and thirty-four cases of calculus in the ureter. With a report of three new cases, 115.
Thomson, W. H. Medical treatment of diabetes, 202.
Townsend, Charles W. A case of pyloric stenosis in an infant, 154; concerning German measles, 403.
Twombly, Edward L. Conservative surgery of the uterine appendages with especial reference to the ovaries, 703.

Vickery, H. F. Use of the sphygmomanometer, 480.

Wadsworth, Richard C. Ultimate results of some gynecological operations at Massachusetts General Hospital, 311.
Walton, G. L. The prevailing conception of degeneracy and degenerate, with a plea for introducing the supplementary terms deviation and deviate, 61.
Warren, J. Collins. Clinical lecture on epithelioma at Massachusetts General Hospital, 57.
Watson, F. S. Choice of operation for prostatic hypertrophy, 453.
Watson, F. S., and Thorndike, Paul. Recent progress in genito-urinary surgery, 93, 125.
White, Leon E. Resection of nasal septum with report of fifteen cases, 419.
Whiteside, G. S. The Caspar-Hirschmann demonstration and photographic cystoscope, 464.
Whitney, William F. A comparative study of the death rates for the State of Massachusetts for the years, 1850, 1875, and 1900, 535.
Williams, Francis H. A comparison between the medical uses of the x-rays and the rays from the salts of radium, 206; notes on radium. Production of the Gamma rays from the Beta rays of radium; use of radium in some diseases of the eye, 559.
Withington, Charles F. Aneurism of the aortic arch, 538.
Worcester, A. Obstetrical nursing, 1.
Wose, A. M. The cystoscope—its diagnostic value, 344.

Young, Ernest Boyen. Supernumerary breasts and nipples, with report and photograph of a case, 319; the intra-abdominal rupture of ovarian cysts, with report of a case, 235.

SUBJECTS.

Alcohol and alcoholism, Cabot, Richard C., 281.
Amputation. Amputation at hip joint, Bolles, W. P., 537.
Anaesthol, 415.
Anesthesia. Prostatectomy,—spinal anesthesia, Lund, F. B., 460.
Aneurism. Aneurism of the aortic arch, Withington, Charles F., 538.
Annual meetings of Massachusetts Medical Society and American Medical Association in conflict, 551.
Appendicitis. A case of appendicitis with general peritonitis, Atwood, Charles A., 347.
Arthritis. Infectious arthritis, Goldthwait, Joel E., 363; differential diagnosis of rheumatism and arthrites, Harrington, Thomas F., 85.
Artificial Feeding. Two simple formulæ for use in the artificial feeding of infants, Kahn, I. Stanley, 296.
Atrophy. Bilateral facial atrophy, with report of a case and its treatment by subcutaneous injection of paraffin, Burley, Benjamin T., 391.

Bicycle. The bicycle as a therapeutic agent, Aldrich, Charles J., 107; the bicycle as a therapeutic agent, Gulick, Luther Halsey, 40.
Biography. Baker, Frank E., 254; Bennet, George H. R., 138; Billington, Cornelius E., 56; Bissell, Philip, 442; Brooks, George Washington, 660; Cornish, Theodore Osgood, 604; Cox, Miller, 496; Dana, Edward Barbillac, Jr., 108; Eidenberg, Anton, 28; Ferguson, James Francis, 56; Fitzmaurice, Thomas J., 578; Foster, George Winslow, 56; Gallison, Jefferson Cushing, 226; Hale, George Clinton, 138; Hammond, George H., 390; Hanna, Edmund S., 108; Hartwell, Benjamin Hall, 56; Holcome, William Frederic, 310; Knight, Moses D., 282; Kohnstamm, Lorenzo J., 470; Krehbiel, August, 198; Liebmann, Carl, 246; Ludlow, Ogden Curtis, 254; Mackay, Bernard, 552; Mason, Edwin Guillard, 604; McDermott, W. J., 310; McGee, William H., 552; Morris, Moreau, 310; Morse, Verranus, 282; Mott, J. Varnum, 108; Moulton, Benjamin Francis, 552; Murphy, Daniel Francis, 138; Otto, John Martin, 28; Pearce, P. Savary, 660; Polk, John Metcalfe, 390; Rankin, William, Jr., 226; Read, Robert McLellan, 470; Reed, Stuart H., 56; Reimar, August F. W., 524; Robinson, Jonathan Henry, 254; Roe, Joseph B., 168; Rooney, Joseph G., 168; Ruggles, Augustus D., 28; Rundlett, Henry Albert, 282; Russell, Howard C., 254; Smith, H. Lyle, 198; Thornton, John Knowsley, 310; Trudeau, Edward Livingston, 524; Truex, Stephen P., 390; Wadsworth, Peleg, 390; Wallace, David L., 254; Walter, Edward, 254; Waterworth, William, 552; Weed, Robert M., 138; Wheeler, Charles Augustus, 198; Wheeler, Edward Reed, 496; White, Charles Warren, 578; Whybrew, Charles T., 282.
Blood-Pressure. Blood-pressure observations in surgical cases, at the Boston City Hospital, Faulkner, William E., 255; blood-pressure observations in surgical cases, at the Boston Children's Hospital, Stone, James S., 262; blood-pressure observations in surgical cases, at the Massachusetts General Hospital, Murphy, Fred T., 264.
Books Received. Abrams, Albert, the blues (splanchnic neurasthenia); causes and cure, 517; Anders, James M., textbook of the practice of medicine, 192; Archinard, P. E., the medical epitome series: microscopy and bacteriology, 544; Ashby, Thomas A., a textbook of the diseases of women, 22; Handler, Samuel Wyllis, uterine and tubal gestation, 48; Bickham, Warren Stone, a textbook of operative surgery, covering the surgical anatomy and operative technique involved in the operations of surgery, 21; Billings, Frank, the practical medicine series of year books, vol. VI, 356; Bishop, E. Stanmore, essentials of pelvic diagnosis, with illustrative cases, 74; Bramwell, J. Milne, hypnotism: its history, practice and theory, 517; Cabot, Richard C., physical diagnosis of diseases of the chest, 219; Caird, Francis M., a surgical handbook, 192; Cheyne, W. Watson, a manual of surgical treatment, 48; Church, Archibald, nervous and mental diseases, 544; Conner, Phineas S., and others, an American textbook of surgery for practitioners and students, 101; Cordell, Eugene Faumleroy, the medical annals of Maryland, 303; von Cullen, Thomas S., adenomyome des uterus, 74; Cunningham, D. J., manual of practical anatomy, 355; Davis, Charles H. Stanley, the self cure of consumption, 597; De Schweinitz, G. E., a textbook of diseases of the eye, 100; Douglas, Richard, surgical diseases of the abdomen, with special reference to diagnosis, 101; Dunglison, Robley, a dictionary of medical science, 436; Edgar, J. Clifton, the practice of obstetrics, 570; Einhorn, Max, diseases of the stomach, 169; Ewing, James, clinical pathology of the blood, 437; French, James Magoffin, a textbook on the practice of medicine, 383; Gould, A. Pearce, elements of surgical diagnosis, 517; Gould, George M., the American year book of medicine and surgery for 1904, 410; Haat, Prof. O., atlas of external diseases of the eye, 99; Haig, Alexander, uric acid as a factor in the causation of disease, 410; Hall, I. Walker, the purin bodies of food stuffs, and the rôle of uric acid in health and disease, 160; Hansell, Howard F., and Sweet, William F., textbook of diseases of the eye, for students and practitioners of medicine, 160; Hare, Hobart Amory, progressive medicine, 437; Head, Gustavus P., the practical medicine series of year books, vol. III, 517; Henderson, Frank L., lessons on the eye, 131; Hirst, Barton Cook, a textbook of diseases of women, 100; Jellett, Henry, a short practice of gynæcology, 383; Kelly, A. O. J., Editor, international clinics, 488; King, A. F. A., King's manual of obstetrics, 627; Lawson, George, diseases and injuries of the eye, with their medical and surgical treatment, 160; Lazarus-Barlow, Walter Sidney, the elements of pathological anatomy and histology for students, 572; Lazarus-Barlow, Walter Sydney, a manual of general or experimental pathology for students and practitioners, 626; Leftwich, Ralph Winnington, on syphonage and hydraulic pressure in the large intestine, 383; Lindsay, James Alexander, lectures on diseases of the lungs and the heart, 572; Luke, Thomas D., anesthesia in dental surgery, 572; Macleod, J. M. H., practical handbook of the pathology of the skin, 354; Martindale, W. Harrison, and Westcott, W. Wynn, the extra pharmacopoeia, 710; Matthews, Joseph M., a treatise on diseases of the rectum, anus and sigmoid flexure, 73; McGlannan, Alexius, the medical epitome series, physics and organic chemistry, 544; McLellon, Errett E., students-aid to muscular attachments, 517; Monro, Thomas Kirkpatrick, manual of medicine, 354; Mosher, J. Montgomery, scheme for the differential testing of nerves and muscles for use in diagnosis, 517; Mumford, James G., clinical talks on surgery, 100; Mummery, P. Lockhart, the after-treatment of operations, 356; Mundell, D. E., anatomy applied to medicine and surgery, 435; Nissen, Hartvig, and Posse, Baroness Rose, rational home gymnastics, 73; Palmer, Margaret D., lessons on massage, 435; Peterson, Frederick, and Haines, Walter S., a textbook of legal medicine and toxicology, 219; Potter, Samuel O., quiz-compends, 436; Proust, A., and Ballet, Gilbert, the treatment of neurasthenia, 571; A. Pichler's Wittwe & Sohn, enzyklopädisches Handbuch der Schulhygiene, 627; Ransome, Arthur, the principles of "open air" treatment of phthisis and of sanitorium construction, 627; Roger, G. H., Roger on infectious diseases, their etiology, diagnosis and treatment, 571; Ruge, Reinhold, introduction to the study of malarial diseases, 333; Salkowski, E., laboratory manual of physiological and pathological chemistry, 544; Savill, Thomas D., a system of clinical medicine, 409; Schaeffer, Oskar, atlas of operative gynecology, 597; Scudder, Charles Locke, the treatment of fractures, with notes upon a few common dislocations, 464; Smith, Major F., modern bullet wounds and modern treatment, with special regard to long bones and joints, field appliances and first aid, 73; Smith, William Johnson, nurses' guide to surgical bandaging and dressings, 101; Starr, M. Allen, organic nervous diseases, 303; Stelwagon, Henry W., treatise on diseases of the skin for the use of advanced students and practitioners, 710; Stevens, A. A., a manual of the practice of medicine, 355; Stewart, Netta, gynecological nursing, 464; Stöhr, Philip, textbook of histology, 101; Sutton, J. Bland, tumors: innocent and malignant, their clinical characters and appropriate treatment, 48; Swanzy, Henry R., a handbook of the diseases of the eye, 100; Toldt, Carl, an atlas of human anatomy, 355; Treves, Sir Frederick, a manual of operative surgery, 436; Vincent, Ralph, the nutrition of the infant, 382; Walsham, William Johnson, surgery, its theory and practice, 73; Wathen, John R., Wathen's epitome of histology, 99; Wheeler, Marianna, plain hints for busy mothers, 464; Whitman, Royal, a treatise on orthopedic surgery, 354; Williams, Chisholm, high frequency currents in the treatment of some diseases, 393; Wilson, J. C., the complete medical pocket-formulary and physician's vade-mecum, 333; Witthaus, R. A., a laboratory guide in urinalysis and toxicology, 544.
Calculus. Removal of calculus in ureter by a new method, Garceau, Edgar, 426; some conclusions based on a study of one hundred and thirty-four cases of calculus in the ureter. With a report of three new cases, Tenny, Benjamin, 115.
Cancer. Cancer of the rectum; combined abdominal and perineal operation, Powers, Charles A., 63; carcinoma basocellulare. A group of

superficial gland-like tumors of the skin, of relatively slight malignancy, including rodent ulcer, Emley, S. C., 611; clinical lecture on epithelioma at Massachusetts General Hospital, Warren, J. Collins, 57.

Catgut. Claudius' iodized catgut, Binney, Horace, 504.

Cholecystectomy. Cholecystectomy, Lund, F. B., 539; remarks upon cholecystectomy and cholecystostomy, with special reference to their comparative safety and efficiency in the treatment of biliary affections, Richardson, Maurice H., 139; cholecystostomy and cholecystectomy. A study of a certain series of operations, Scudder, Charles L., 145.

Chorea. A many-phased case of chorea; Marion, Horace E., 397; a case of Huntington's chorea; its social aspects, Putnam, J. J., 399.

Correspondence. Alcohol and alcoholism, Cabot, Richard C., 281; anaesthol, 415; a national society for study of tuberculosis, 361; annual meetings of Massachusetts Medical Society and American Medical Association in conflict, 551; an unauthorized label, 415; "arrested tuberculosis." Should unproved cases be thus recorded? Lord, Frederick K., 294; arrested tuberculosis: subsequent histories of cases treated at the Sharon sanatorium, Bowditch, Vincent Y., 308; credit where credit is due, 337; imposter, Blodgett, Albert N., 167; John Wesley's life-long capacity for work, 495; leprosy in Massachusetts, 550; letter from Upper Egypt, F. M. G., 137; mammeata, 337; morphine and menstruation, Howard, William Lee, 167; sanitarium viz. sanatorium, 577; the bicycle as a therapeutic agent, Aldrich, Charles J., 107; the embryological collection of the Harvard Medical School, Minot, Charles S., 107; the graphophone in therapeutics, 389; the medical register for New England, Brown, Francis H., 55; the game of quarantine as played at Naples, Smith, James A., 607; technical terms may be misinterpreted, 603; die Bedeutung der Lumbalpunckticn für die Psychiatrie von Prof. Nissl (Heidelberg), McDonald, William, Jr., 658; annual meeting, American Medical Association, June 13, 1904, Page, Calvin G., 687; sanitarium *vs.* sanatorium, Miller, A. Erskine, 687; the National Association for the study and prevention of tuberculosis, 714.

Cystoscope. Use of cystoscope in determining what operation is advisable in prostatic hypertrophy, Balch, Franklin G., 457; the Caspar-Hirschmann demonstration and photographic cystoscope, Whiteside, G. S., 646.

Cytotoxins. Cytotoxins and cytotoxic immunity, Ehrlich, Paul, 448.

Death-Rate. A comparative study of the death-rates for the state of Massachusetts for the years 1850, 1875 and 1900, Whitney, William F., 535.

Decapsulation. Report of cases of decapsulation of the kidneys, Balch, Franklin G., 90; nephrocapsulectomy, Blake, J. B., 539; a second case of puerperal eclampsia successfully treated by renal decapsulation, Edebohls, George M., 586; decapsulation of the kidneys, Hubbard, Joshua C., 93; decapsulation of the kidneys, Reynolds, Edward, 122.

Degeneracy. The prevailing conception of degeneracy and degenerate, with a plea for introducing the supplementary terms deviation and deviate, Walton, G. L., 61.

Dermatology. Report on dermatology, Bowen, John T., 484; clinical report from the ward for skin diseases at the Massachusetts General Hospital, Bowen, John T., 564.

Deviation. The prevailing conception of degeneracy and degenerate, with a plea for introducing the supplementary terms deviation and deviate, Walton, G. L., 61.

Diabetes. The general management of diabetes, Shattuck, Frederick C., 199; medical treatment of diabetes, Thomson, W. H., 202.

Editorials. The transmission of plague, 23; report of Massachusetts Hospital for epileptics, 24; distribution of insanity, 24; tuberculosis in New York police department, 25; final report of the royal commission upon arsenical poisoning, 49; a meeting in Baltimore to discuss the tuberculosis congress situation, 50; health commissioner of New York, 51; the Boston association for the relief and control of tuberculosis, 51; the financial problem of the New York hospitals, 75; obliteration and substitution, 76; trypanosoma and trypanosomiasis, 102; the menstrual functions of the morphine habitué, 103; diphtheria antitoxin, 104; medical investigation in the Philippines, 132; insanity among negroes, 132; paralysing parsimony, 133; the multiplication of scientific journals, 133; interscholastic sports, 161; report of state board of health of Massachusetts, another organism in carcinoma, 163; testing of clinical thermometers, 163; annual report of Harvard University, 192; etiology and pathogenesis of pancreatic lithiasis, 194; study of rinderpest in the Philippine Islands, 195; antitoxin: cost of production, 196; premature burial, 220; a medical member of the Panama Canal Commission, 221; Bacillus prodigiosus, 248; politics and public health, 249; health of imperial Japanese navy, 250; microbes in books, 250; the Massachusetts school for feeble-minded, 276; the islands of Langerhans, 277; dusty streets, 304; report of public health and marine hospital service, 304; interscholastic sports, 305; intracranial surgery, 333; the Boston dispensary, 335; the visit of Prof. Paul Ehrlich, 356; catheterization of the ureter, 357; the etiology of spina bifida, 359; an explosive outbreak of typhoid fever, 384; disinfection of dwellings, 384; Pullman cars and money, roots of evil, 385; something about shoes, 386; co operative medical work, 411; typhoid epidemic at Watertown, N. Y., 412; influence of tramps in spreading smallpox, 412; specialized surgery, 437; report of Massachusetts General Hospital, 438; interchange of medical teachers, 465; intermediate repair of injuries of childbirth, 465; Cesarean section at Boston Lying-in Hospital, 466; proposed new Bellevue Hospital, 467; use of public institutions for clinical instruction, 489; medical education in America from a British standpoint, 490; report of Boston Insane Hospital, 491; minimum proteid requirement of the healthy man, 518; leprosy in Massachusetts, 519; patent medicine curse, 520; the absence of eosinophile cells in pus, 545; report of cancer research fund, 546; American Social Science Association, 546; meeting of the American Gynecological Society, 547; laboratories of pathology and pharmacology at the University of Pennsylvania, 573; development of free public baths, 574; bulletins of the Oregon state board of health, 574; award of the Warren triennial prize, 575; newer methods of water purification, 598; report of the Massachusetts state board of insanity, 599; mental disease in general hospitals, 600; annual report of the Surgeon-General of the United States, 601; annual meeting of the Massachusetts Medical Society, 627; the development of the private hospital, 628; extinction of rabies in Great Britain, 629; new buildings at the Boston City Hospital, 629; Dr. Osler on Immortality, 655; the international congress of arts and sciences, 656; the Rockefeller Institute for Medical Research, 657; report of royal commission upon human and animal tuberculosis, 683; dedication of the new laboratories at the University of Pennsylvania, 684; consumption in New England, 711; a departure in the training of nurses, 712; the Fourth of July, 713.

Embryological collection of the Harvard Medical School, Minot, Charles S., 107.

Enterostomy. Enterostomy in peritonitis, Greenough, Robert B., 525.

Epilepsy. Report of cases of trephining for epilepsy, Munro, John C., 109; a contribution to the pathology of hysteria based upon an experimental study of a case of hemianesthesia with clonic convulsive attacks simulating Jacksonian epilepsy, Sidis, Boris, Prince, Morton, and Linenthal, H., 674; a case of labor in an epileptic, Hamilton, Annie Lee, 680.

Eye-strain. Eye-strain considered as a factor in production of lateral curvature of spine (preliminary communication), Kilburn, Henry W., 318.

Finsen Light. The Finsen light cure, Stewart, H. John, 16.

Graphophone in therapeutics, 389.

Gynecology. Recent progress in gynecology, Burrage, W. L., 326, 348; a case of ovarian tumor with twisted pedicle. Three reductions without operation. Operation; recovery, Porter, Charles Allen, and Quinby, William Carter, 375; ultimate results of some gynecological operations at Massachusetts General Hospital, Wadsworth, Richard G., 311; the intra-abdominal rupture of ovarian cysts, with report of a case, Young, Ernest Bowen, 235; supernumerary breasts and nipples, with report and photograph of a case, Young, Ernest Bowen, 319; a case of labor in an epileptic, Hamilton, Annie Lee, 680; conservative surgery of the uterine appendages with especial reference to the ovaries, Twombly, Edward L., 703.

Heart. Cardiac displacement, Stone, Arthur K., 29.

Hemopericardium. A case of traumatic hemopericardium, Morse, John Lovett, 240.

Hemorrhage. A case of traumatic cerebral hemorrhage, Atwood, Charles A., 325; three cases of hemorrhagic disease of the new-born, Stevens, Henry B., 565.

Hernia. Radical cure of inguinal hernia, O'Conor, John, 374.

Herter Lectures. Erhlich, Paul, 443.

Hydrotherapy. Hydrotherapeutic prescriptions, Pratt, Joseph H., 288.

Hygiene. Progress in public hygiene, Abbott, Samuel W., 376, 404.

Hysteria. A case of hysteria, Baldwin, H. C., 185; a contribution to the pathology of hysteria based upon an experimental study of a case of hemianesthesia with clonic convulsive attacks simulating Jacksonian epilepsy, Sidis, Boris, Prince, Morton, and Linenthal, H., 674.

Hystero-neuroses. Hystero-neuroses and their relation to the physical examination of all women patients, Craig, Daniel H., 497.

Idiocy. Contribution to the etiology of idiocy and imbecility, Bullard, William N., 471; arrest of development, probably resulting from congenital syphilis, Larrabee, R. C., 540.

Immunity. Physical chemistry *v.* biology in doctrine of immunity, Ehrlich, Paul, 454; cytotoxins and cytotoxic immunity, Ehrlich, Paul, 448.

Intussusception. Some cases of intussusception, Balch, Franklin G., 39.

Laminectomy. Laminectomy for fractured spine, Lund, F. B., 540.

Laryngology. Recent progress in laryngology, Coolidge, A., Jr., 186, 212.

Lateral Curvature. Forcible correction in lateral curvature of the spine. Fourth paper, Lovett, Robert W., 283; eye-strain considered as a factor in production of lateral curvature of spine (preliminary communication), Kilburn, Henry W., 318.

Leprosy in Massachusetts, 550.

Ligature. Experiments with the McGraw elastic ligature, Murphy, Fred T., 81.

Mammeata, 337.

Measles. German measles, Montgomery, F. H., 510; concerning German measles, Townsend, Charles W., 403.

Medical Notes, 25, 51, 76, 104, 134, 164, 196, 222, 250, 277, 306, 335, 359, 386, 412, 439, 467, 492, 521, 547, 575, 601, 630, 657, 685, 713.

Medical Register for New England, Brown, Francis H., 55.

Meningitis. Tubercular meningitis in adults, Jackson, Henry, 501; typhoid fever in infancy, with report of case complicated with meningitis terminating in recovery, Sylvester, Charles P., 321.

Mercuric Cyanide. Mercuric cyanide as a surgical disinfectant, Harrington, Charles, 43.

Miscellany, 28, 54, 78, 107, 135, 166, 198, 223, 253, 280, 308, 337, 361, 388, 414, 441, 469, 493, 524, 550, 577, 603, 632, 660, 686.

Monoplegia. Two cases of crural monoplegia of traumatic origin, Putnam, J. J., 481.

Morphine. A new treatment for morphine addiction, Birge, William S., 401; morphine and menstruation, Howard, William Lee, 167.

Myxedema. Myxedema, Larrabee, R. C., 540.

Nasal Septum. Deviation of nasal septum, Coolidge, A., Jr., 478; resection of nasal septum with report of fifteen cases, White, Leon E., 419.

Needle Holder. A new needle holder, Keefe, John W., 297.

Neurasthenia. The partial passing of neurasthenia, Dana, Charles L., 339; the relation of some special causes to the development of neurasthenia, Edes, Robert T., 227.

Obituaries. Joshua Little Hale, 54; In memoriam — William Ingalls, 106; Ambroise A. Liebault, 361; resolutions on the death of Dr. Charlotte Blake Brown, 523; Roberts Bartholow, 549; Sir Henry Thompson, 549; a tribute to Benjamin H. Hartwell. By the Massachusetts Medico-Legal Society, 576; Professor Wilhelm His, 631; Nathan Smith Davis, 714.

Obstetrics. An account of the work, including obstetrical technique, at the Lying-In Hospital of the City of New York, Bradley, Charles H., 293; a second case of puerperal eclampsia successfully treated by renal decapsulation, Edebohls, George M., 586; the use of obstetric forceps, Gilman, Warren R., 182; a case of labor in an epileptic, Hamilton, Annie Lee, 680; report on obstetrics, Higgins, Frank A., 242, 272; vaginal section in the treatment of extra-uterine pregnancy, Higgins, Frank A., 561; on some questions relative to extra-uterine pregnancy, with especial reference to tubal abortion, Storer, Malcolm, 5; cesarean section for placenta previa in a primipara, Swift, William N., 65; obstetrical nursing, Worcester, A., 1.

Ophthalmology. Ligation of lachrymal canal to prevent infection following cataract extraction, Quackenboss, Alex., 347.

Patella. Slipping or recurrent dislocation of the patella. With the report of eleven cases, Goldthwait, Joel E., 169.
Peritonitis. A case of appendicitis with general peritonitis, Atwood, Charles A., 347; enterostomy in peritonitis, Greenough, Robert B., 525.
Pleurisy. The prognosis of idiopathic pleurisy, Sears, George G., 209.
Prostate. Use of cystoscope in determining what operation is advisable in prostatic hypertrophy, Balch, Franklin G., 457; a brief résumé of present status of treatment of enlarged prostate, Cabot, Arthur Tracy, 458; results of operations upon prostate, Massachusetts General Hospital, from Jan. 1, 1892, to July 1, 1893, Cabot, Hugh, 456; gross pathology and mechanism of prostatic obstruction, Chute, Arthur L., 451; surgical anatomy of the prostate, Crandon, L. R. G., 450; perineal prostatectomy, Harrington, F. B., 482; prostatectomy. — Spinal anesthesia, Lund, F. B., 460; choice of operation for prostatic hypertrophy; Watson, F. S., 453.

Radium. A comparison between the medical uses of the x-rays and the rays from the salts of radium, Williams, Francis H., 206; notes on radium. Production of the Gamma rays from the Beta rays of radium: use of radium in some diseases of the eye, Williams, Francis H., 559.
Recent Progress. Report on pediatrics, Rotch, T. M., and Morse, J. L., 43, 66, 621; recent progress in genito-urinary surgery, Watson, F. S., and Thorndike, Paul, 95, 125; recent progress in laryngology, Coolidge, A., Jr., 186, 212; report on obstetrics, Higgins, Frank A., 242, 272; report on thoracic disease, Bartol, J. W., 297; recent progress in gynecology, Burrage, W. L., 326, 348; progress in public hygiene, Abbott, Samuel W., 376, 404; report on pathology, Pratt, Joseph H., 427; report on dermatology, Bowen, John T., 484; the progress of surgery, Burrell, Herbert L., and Cushing, Hayward W., 511, 541, 566, 589; progress in otology, Hammond, Philip, 706.
Resorcin. Action of resorcin, Clark, F. C., 483.
Rheumatism. Differential diagnosis of rheumatism and arthrites, Harrington, Thomas F., 85.

Sanitarium viz. sanatorium, 577, 687.
Septicemia. Septicemia from the Bacillus mucosus capsulatus, Post, Abner, 536.
Septic Wounds. Some clinical observations on care of septic wounds, Chute, Arthur L., 423.
Societies. American medical association. Section on practice of medicine, 650, 681, 708; American public health association, 19, 45; association of American physicians, 593, 623; Boston society of psychiatry and neurology, 189, 217, 351; Boston society for medical improvement, 217, 299, 516; northwestern branch of the Philadelphia county medical society, 329; medical society of the State of New York, 215, 245; New York academy of medicine, 380; New York neurological society, 300, 487, 513; obstetrical society of Boston, 17, 247, 408, 570; Suffolk district medical society, 126; Suffolk district medical society, section for surgery, 155, 462; the American society of clinical surgery, 353; the medical association of the greater city of New York, 274, 431; the southern surgical and gynecological association, 68, 96, 128.
Sphygmomanometer. Use of the sphygmomanometer, Vickery, H. F., 480.
Spleen. A case of ruptured spleen; operation and recovery, Brewster, G. W. W., 211.
Status Lymphaticus. Finney's operation for pyloric stenosis: sudden death in status lymphaticus, Mumford, James G., 482.
Stomach. Gastric ulcer, Buckingham, E. M., 538; Finney's operation for pyloric stenosis: sudden death in status lymphaticus, Mumford, James G., 482; cardiac displacement, Stone, Arthur K., 29.
Suicide. An attempted suicide by illuminating gas, Holyoke, Frank, 324; the relation of the burn to the bullet hole as evidence of homicide vs. suicide: report of the Nagle case, Perkins, Jay, 616.
Sulphurous Acid. Sulphurous acid and its salts as food preservatives, as aids to fraud, and as possible causes of lesions of the kidneys, Harrington, Charles, 555.
Surgery. Amputation at hip joint, Bolles, W. P., 537; the progress of surgery, Burrell, Herbert L., and Cushing, Hayward W., 511, 541, 566, 589; a sigmoid band of unusual origin. Operation. Relief, Chute, Arthur L., 476; bullet wounds of the head, chest and abdomen, Cushing, H. W., 538; a case of ovarian tumor with twisted pedicle. Three reductions without operation. Operation; recovery, Porter, Charles Allen, and Quinby, William Carter, 375; cholecystostomy and cholecystectomy. A study of a certain series of operations, Scudder, Charles L., 145; conservative surgery of the uterine appendages with especial reference to the ovaries, Twombly, Edward L., 703.

Thermometer. Disinfection of the clinical thermometer, Denny, Francis P., 585.
Thyroidectomy. Thyroidectomy for exophthalmic goiter; obstruction of the superior vena cava, Jackson, James Marsh, 185.
Tuberculosis. A national society for study of tuberculosis, 361; "Arrested tuberculosis." Should unproved cases be thus recorded? Lord, Frederick K., 224; concerning danger of infection in attendants of tubercular patients, Bishop, Louis Faugeres, 507; tubercular meningitis in adults, Jackson, Henry, 501; a case of tubercular contagion, Palmer, Sarah Ellen, 588; human slavery as a prevention of pulmonary consumption, Mays, Thomas G., 647; arrested tuberculosis: subsequent histories of cases treated at the Sharon sanatorium, Bowditch, Vincent Y., 308; the significance of the tuberculosis crusade, and its future, Otis, Edward O., 694.
Typhoid Fever. Typhoid fever in children, Baginsky, Adolf, 10; typhoid fever in infancy, with report of case complicated with meningitis terminating in recovery, Sylvester, Charles P., 321.

X-rays. A comparison between the medical uses of the x-rays and the rays from the salts of radium, Williams, Francis H., 206.

OBSTETRICAL NURSING.*

BY A. WORCESTER, M.D., WALTHAM, MASS.

In obstetric practice, at least in normal cases, more depends upon the nurse than upon the obstetrician. And even in the extraordinary cases, however able and faithful the obstetrician may be, unless the nurse is well trained, his patients are very liable to suffer unnecessary discomforts and are also exposed to gravest dangers.

The provision of an adequate supply of properly trained obstetrical nurses is or should be a matter of great interest to obstetricians, and I therefore make no apology in again bringing the subject to your attention.[1] It is true that the responsibility of training nurses is rapidly being assumed by nurses. This is as it should be. But it is also fitting that the scope and character of the education and training required in the different special lines of nursing should be agreed upon and set forth by the physicians and surgeons practicing these specialties. Nor is this so difficult of accomplishment as at first thought it might appear to be. In spite of the varying methods and practices of obstetricians in different schools and in different localities, there is nevertheless a sufficiently substantial unanimity regarding the principles involved, and clearly defined ideals for the education of obstetricians have already been formulated. And so there surely can be no insurmountable obstacle to securing at least equally well defined ideals for the education of the obstetricians' lieutenants.

In attempting to formulate these ideals the main question confronting us is that of the proper functions of the obstetrical nurse. And in order to discuss this question intelligently we must have in mind the different stages already attained in her evolution.

When the Pilgrims were sojourning in Amsterdam before their departure for the new world they engaged a deaconess midwife "to serve diligently the sick and the weak, especially the women according to their needs." I have not yet been able to find out if this important personage crossed the ocean with them. But it is certain that among both the Pilgrims and the Puritans the obstetric art for nearly two centuries was practised only by midwives. In this as in many other ways the old English customs survived in New England long after their disappearance in the former homes of our race. You may remember the story of Dr. Boylston, who in the eighteenth century came back from Europe to Salem a trained obstetrician, only to wait ten years before he was allowed a single opportunity to deliver a woman. On the island of Nantucket my great grandmother was one of the first to venture to employ a physician's help in her labors. But in the early years of the last century, after her example had been generally followed and most of the children so helped into the world were swept away by an epidemic of "putrid sore throat," it was held to be a visitation of God's wrath because of the shamelessness of their mothers. For a long time afterwards no woman on the island dared to employ an obstetrician.

In the larger towns there were midwives in these early days, but in the country until within recent years it was the custom for the woman in labor to depend upon the help of neighboring women. And in every community there were some who were held to be especially skilled in giving the needed assistance. My own mother during her lifetime, besides giving birth herself to twelve children, had given neighborly aid at nearly one hundred births. On many of these occasions no physician was present. There were no telephones or automobiles in those days. And unless the labors were delayed and difficult the chances were large against the physician's attendance at the crisis. Such was the predicament when I myself arrived. I now understand what our old washerwoman used to say when as a mischievous boy I splashed the suds at her — "And me that spanked the life into you, you brat, and I'm damned sorry I ever did."

Out of this neighborly volunteer service, which now has for the most part disappeared, there grew the custom of employing regularly monthly nurses, women generally well past middle age, widows often or staid spinsters who by accident rather than by design had acquired more or less experience in such service. In them was gathered the traditions and experiences of former generations, much of it wrong, but some of it not to be despised. Many of these old-timers are still in harness. In many of our New England towns no other nurses are available. Very fortunately for the families of moderate means, who never can afford the luxury of modern trained nurses, there is still a continuous supply of these women helpers. And owing no doubt to the change of opinion regarding the proper age qualification of nurses, young women nowadays take up this trade of monthly nursing. Prevented by one reason or another from taking regular professional training, and attracted by higher wages than can be otherwise earned, they soon pick up the trade. Often they give excellent service not only in nursing the mother and baby, but in doing the housework as well.

Most of the obstetrical nursing in New England is still done by these untrained nurses. And much might be done to improve the character of their service with very little effort or expenditure. Of this possibility I shall speak later on. But I want now to speak of the midwives. There have never been many of them in this country. And now, except among our foreign-born population, they have almost no practice. No school for midwives, so far as I am aware, has ever made headway on this side the ocean. The practice of midwifery once assumed by the physicians has remained for a century in their hands. And only

*Read at a meeting of the Obstetrical Society of Boston, Oct. 20, 1903.

[1] Vide Reports of Obstet. Soc. of Boston, in Boston Med. and Surg. Jour., May 3, 1894, and Dec. 1, 1898.

lately, and even now only in the larger cities, have any physicians ventured to refuse such practice.

It would be profitless to lament any such well-marked tendency in the evolution of our civilization. And yet in contemplating the elimination of the midwife it is well worth our while to consider if no advantages have been so sacrificed. For certain it is that the medical profession is responsible for the midwife's disappearance. Without help from medical societies and institutions the midwife cannot obtain her necessary education, and without the co-operation of medical practitioners she cannot succeed in practice.

It would be very pleasant to believe that the failure to provide such education and to offer such co-operation has been wholly due to the belief that modern science requires in the practice of midwifery a full medical education. But is it not too possible that physicians have preempted this field of service in order more quickly to gain large and remunerative family practice, and have not many men who really hated midwifery undertaken it simply for this purpose? We must admit that the well-trained midwives on the other side of the ocean still give excellent service, and that the honor of many of the improvements in the art belongs to them. Granting all that can be claimed regarding the necessity for the greater skill and strength and higher education of surgical obstetricians in abnormal and complicated cases of childbirth, it may well be questioned if in the conduct of normal and natural labors the midwife does not give equally good service. The midwife certainly gives more time than the physician can who has besides to meet the demands of his general practice. She can well afford to charge for the case much less, and she also saves the family from much of the expense for the nursing needed where a physician is the accoucheur. Moreover, there is intrinsic fitness in woman's service to woman's needs. No one would probably advocate or desire any return to the old-fashioned notions of the indelicacy, if not the indecency, of women's having men's help, even where such help alone can save their health and lives. But we are considering cases where women helpers could serve just as well. And in absolutely normal cases of childbirth it is at least possible that sisters can serve their sisters better than brothers can. They might not prepare so extensively for all possible emergencies; and so they might not impress their importance upon terrified families and thus prepare them for a tremendous bill of expense. Where there is unlimited wealth for only a single heir of course no one would think of employing a midwife, but in families where the children come faster than the dollars, and where the poor mother needs little help in her labor but much in her household, the midwife fits in admirably. But the midwife, useful as she was and still might be, has forever lost her place in the onward march of our race. And it remains for us only to make sure that no advantage that belonged to her service shall be lost. To this part of our subject we shall return.

We have now brought into passing view three kinds of obstetrical nurses, the neighborly helpers, the regular untrained monthly nurses and the midwives. By far the larger part of the obstetrical nursing of this country is still done by these kinds of nurses. In the cities, especially among the foreign born, the midwife still holds sway. As has lately been brought to our attention by Dr. J. G. Blake, there is great need of some official regulation of the midwife's service. But with no opportunity offered for her education it will be difficult for the state to insist upon any educational requirements for giving her a license.

In the towns the untrained nurses occupy the field. They are improving in their methods and in their efficiency. But much more might be done for their improvement.

In the sparsely settled country women in childbirth still depend upon the nursing that kindly neighbors can give them. Without any scientific knowledge, and with only stray bits of information to guide them, these good-hearted helpers do surprisingly well. One cannot help regretting the disappearance of this neighbor nursing. No amount of education in the obstetrical nurse can ever make up for the lack of true neighborly kindness. But there is no necessity for such loss, if its importance is insisted upon in the training of our modern nurses, whose service in obstetrical nursing we have now to consider.

Many of us remember the brave beginning in this country, made a third of a century ago at the New England Hospital for Women and Children, in training nurses. To that hospital belongs the honor of having given the first American diploma of nursing to one [2] who afterwards proved her worth as the first superintendent of the Massachusetts General Hospital and the Boston City Hospital training schools, and of at least a dozen others. Nurses of course had been trained previously in all hospitals since their foundation, but only for the advantage of the hospitals. It was a distinctly forward step when systematic training was offered to women looking to their greater usefulness in the community afterwards. But not until recently has it been considered necessary in the hospital training schools to offer anything more than the opportunities afforded by experience. I myself have the honor of having given the first class instruction in obstetrical nursing to student nurses at the Boston Lying-in Hospital in the summer of 1883. Since then the improvement in the training given in the different schools as well as the number of training schools has made great headway. It would be beyond the limits of my present purpose even to recount these advances. But it would be easier to leave out of consideration the general hospital training schools where perhaps the course includes a lecture or two upon midwifery, were it not for the fact that many of the graduates of these schools, relying upon their knowledge of nursing fevers and fractures, have presumed to offer themselves as trained nurses in obstetrical cases. Such nurses have done much

[2] Miss Linda Richards.

to retard the acceptance by physicians and families of the great advantages of trained nurses in such service. And yet the supply of obstetrical nurses who have been properly trained is still so small that any interference with the growth of the demand for their services may be overlooked.

Within very recent years, however, the leaders of the large hospital training schools have begun to recognize the obligation of giving to their student nurses regular instruction and practice in obstetrical nursing. To this end most serviceable relations have been established between the general and the maternity hospitals whereby student nurses in the one have periods of service in the other. And the time probably is not far distant when every school that pretends to offer a thorough education in nursing will include arrangements for such service.

The schools connected with small hospitals, on the other hand, although not yet recognized at their real worth, have always included obstetrical nursing in the course of training given. Such schools are rapidly increasing in number and in importance. Many of them are striving in every way to follow educational ideals, and they welcome any suggestions regarding their improvement. The times are therefore ripe for the establishment by obstetricians of standards for the education of obstetrical nurses. Upon this subject, in offering the following propositions, I invite discussion:

In the first place I trust that it may be agreed that a general training is prerequisite. Specialists in the practice of medicine are all very well; if complications arise other specialists can be brought in. But even specialists in medicine must have had a general medical education, and it is all the better for their patients if they have had some general practice besides. But in nursing service it is no such easy matter to secure different nurses as complications arise. And in any case of midwifery, knowledge of the nursing required in fevers and in surgical operations may be as needful as knowledge of obstetrical nursing.

In the next place, as regards the scope and character of the education required in obstetrics, I can hardly hope for equally general agreement to my proposition that the obstetrical nurse should have at least as much as is provided for midwives in their best schools. It may be feared by some that such training would make midwives. Not at all. No student nurse of to-day could possibly be induced to undertake the practice of midwifery. The higher her education the less willing she would be to undertake such responsibility. The whole trend of modern nursing is against such a course, and in its professional advance the foundation principle becomes more and more clear that the nurse is the physician's executive officer. It is her duty and her delight not to interpret the symptoms but to observe and record them, not to decide upon the course of treatment that shall be pursued but to carry out the orders. And yet in midwifery work one can never be sure that the obstetrician will be at hand as emergencies occur which require instant action, or even at the crisis of delivery. Moreover, the well-trained obstetrical nurse is often employed simply as a guard against these contigencies in families where the luxury of the constant attendance of an obstetrician during much of the pregnancy and all of the confinement cannot be afforded. There surely can never be found valid reasons for limiting the amount of obstetrical knowledge of the nurse. The more she has the better. Those who harbor such dread of education in nurses have probably had experience not with the really well educated but only with the poorly trained, whose ignorance accounts for their intolerable officiousness.

Before asking assent to my proposition that the obstetrical nurse should have at least as much education as is furnished in the schools for midwives, I ought first to explain what that education is. It will be sufficient perhaps to quote some of the questions asked in the examinations held by the Obstetrical Society of London before granting their certificate that the candidate is in their opinion "a skilled midwife competent to attend natural labor":

(1) "Describe the passage of the fetus through the pelvis with the face presenting and the chin to the right, and say how you would diagnose the presentation, and in what cases you would send for medical assistance.

(2) "Give mechanism of labor in breech presentation with the left buttock backwards and to the left.

(3) "How would you manage a twin labor?

(4) "Describe the natural appearances of a child's motions during the first week of life. What unnatural appearances are the most usual and what do they show?

(5) "Give the causes and treatment of retained placenta.

(6) "What is the difference between unavoidable and accidental hemorrhage? What would be your treatment in each case?"

If these sample questions seem to imply an impossible standard of education for obstetrical nurses, I can offer my own experience in having fitted a student nurse to pass with honor the examination from which the above questions are quoted.

It may be questioned why nurses need be taught how to conduct a normal labor when it is intended that such responsibility shall always as far as possible be avoided by them. This question forces upon us the consideration of the proper functions of obstetrical nurses. Disagreement is now inevitable. Nevertheless, we must try to reach some agreement in the hope that out of our discussion some progress will be made. And at any rate it behooves those who have definite ideas upon the subject to state them.

I myself believe that the obstetrical nurse should be expected to visit her pregnant patient occasionally, to advise her about all the preparations for her expected confinement, including the baby's wardrobe, and to listen carefully to all her woes and complaints, informing the obstetrician

from time to time of the exact condition of his future patient.

Against this idea of the nurse's function some physicians may believe that these duties belong to them. If the physician prefers to give this sisterly service, let him give it; that should not prevent other physicians having nurses' help in such business.

As the time of the expected labor draws near I believe the nurse should be expected to make sure that the patient is in normal condition, and to report to the physician any deviations from the normal. It is as easy and proper for the nurse as it is for the physician to make sure of the proper action of the kidneys, for instance; nor will a properly trained nurse be any more likely to frighten the patient in so doing.

When labor actually begins it is the nurse's function to decide and report that fact; and during the first stage of the labor it is her function to keep watch of its progress, to give assurance that the conditions are normal, and to report to the physician accurately. During the second and third stages of the labor, in event of the physician's absence, the nurse should be able to manage the natural delivery. She should be able to recognize dangerous complications in order that other medical aid may be secured while waiting for the expected physician. In sudden emergencies she should be able to apply the immediate appropriate treatment.

With the help of such nurses the obstetrician's work is made easy. His knowledge and skill and strength can then be far better employed than when, without such nursing service, he has to dally in the lying-in chamber for days at a time or else keep making unnecessary visits in order to be at hand later on when really needed. But it is not merely for the obstetrician's convenience that such nursing ability is advocated. For the patient herself it is in every way an advantage. During the first stage of the labor, for instance, no physician, unless perchance he is himself a nurse in male attire, can so well as the nurse give the needed service; he is only in the way. Furthermore, for busy practitioners such employment of their time is wholly impracticable. Regarding the function of the obstetrical nurse in the confinement period, there is so much less chance for disagreement that nothing need be said beyond calling attention to the great importance both to mother and child of intelligent and devoted nursing service.

To recapitulate, obstetrical nurses should be expected to exercise precautionary surveillance during the pregnancy, to manage the first stage of labor, to recognize any abnormal occurrence, to be able to conduct a normal labor, to apply appropriate preliminary treatment in emergencies, and in the confinement to care for both mother and baby intelligently.

If these are admitted to be her proper functions, there can be no question as to the kind of education needed by the obstetrical nurse. But this is far from all that should be provided for in the ideal education of obstetrical nurses. Important as it is to include this technical knowledge of midwifery, it is equally important in supplanting the old time neighborly helpers and the untrained nurses to preserve all the advantages belonging to their services. The nurses of the future must therefore be taught how to fit in most helpfully in homes where the mother is under temporary eclipse. To this, my third proposition, I am sure all will agree. The nurse must be taught how to utilize all sorts of make-shift material, how to save every unnecessary expense and how to make the family and even the servants her friends, thankful for her having come into the household.

It is needless to say that these all-important lessons can be neither taught nor learned in hospital wards, where the mother with her newborn baby is merely one in a long row, unnamed and unknown except perhaps for some interesting physical abnormality. How can it ever be expected that a nurse whose only training has been in the wards should know anything about home nursing? She has never had anxious husbands and terrified little children and cranky servants to deal with. Very likely she has never even seen the mother's joyous welcome of her child. So she does her utmost to change the home into a hospital, she delights in a large display of paraphernalia, she establishes rigorous rules for visitors and graciously allows the father and little brothers and sisters one at a time to see the baby for a few minutes after the fifth day. In short, the modern hospital-trained obstetrical nurse too often does everything she possibly can to magnify and distort the normal process of childbearing into an unnatural, extraordinary experience. But she is not to blame for so doing, as she is merely following most conscientiously the wrong teaching she has received. Of course it often is possible for her to learn better ways, but the nurse whose only obstetrical training has been in hospital wards will always be at a disadvantage in comparison with the obstetrical nurse who has been trained in home nursing.

In the maternity hospitals and in the out-patient midwifery service the education of medical students naturally enough is of first importance, and nurses, however well trained as assistants of medical students, cannot be expected to have acquired a proper education. The schools of nursing must provide courses of instruction in obstetrics, and clinical practice under capable teachers, where the education of the nurse is the matter of first and not of secondary importance. In the immediate neighborhood of the medical schools it may not seem easy to arrange such educational opportunities for nurses; but even in such cities there is no lack of midwifery cases where medical students would not be admitted, but where the services of student nurses would be a blessing both to the families and to the physicians in charge.

All that is wanting is the organization of proper courses in obstetrical nursing by the regular training schools. The class work and preliminary drill, including practice upon the manikin and

upon the living model, can be easily provided for at the school. And opportunities for clinical practice can be arranged for in connection with the visiting nursing societies which are now to be found in almost every village and town. These societies would gladly undertake more visiting midwifery work could they afford to do so. Now while under the necessity of hiring graduate nurses for this purpose it is not possible for them to comply with the demand. But with student nurse service available many of these visiting nursing associations could well afford to employ a superintendent nurse competent to teach obstetrical nursing. She might well be one of the faculty of the school supplying the nurses, and so the school might maintain full control over the squads of student nurses sent out on this service.

Such an arrangement as this would afford many great advantages. In the first place the needs would be met of the very poor women and of those who can pay only small fees for nursing service. Again, better methods of helping women in childbirth and in confinements would pervade the community; the untrained nurses who now supply this field, if their co-operation is as cordially welcomed as it should be, would soon learn the new and safer ways. And finally under such an arrangement the best possible opportunities would be provided for the education of obstetrical nurses.

ON SOME QUESTIONS RELATIVE TO EXTRA-UTERINE PREGNANCY, WITH ESPECIAL REFERENCE TO TUBAL ABORTION.*

BY MALCOLM STORER, M.D., BOSTON,

Gynecologist to the Carney Hospital and the Boston Dispensary; Gynecologist to Out-Patients at St. Elizabeth's Hospital.

I HAVE been led to prepare this paper by the hope that discussion may throw some light upon certain questions relative to the diagnosis, treatment and after history of this condition that are at present by no means entirely settled in my own mind.

(1) *Diagnosis*, the classical symptoms — amenorrhea, followed by more or less continued irregular flowings, sudden and severe typical pain, usually described as "colicky," expulsion of decidual tissue and the presence of an ill-defined pelvic tumor distinct from a uterus that is not enlarged enough to correspond with the putative duration of pregnancy, combined with anemia and the symptoms suggestive of pregnancy — would if present give are asonable certainty to the diagnosis of a ruptured tube. In my experience, however, the great trouble has been that most of these symptoms are generally absent and especially so in cases of tubal abortion (*i. e.*, discharge of the fetus through the osteum abdominale without rupture of the tube), while in the cases of the rupture of more advanced tubal gestations the patient is very apt to be first seen in a state of collapse too profound to admit much questioning as to symptoms.

I have operated upon seventeen cases of extrauterine pregnancy and diagnosed correctly quite a number more that I had to send to other men for operation. Needless to say, in several of my cases the correct diagnosis was not made until the abdomen was opened. In all these I can recall very few in which even a majority of the classical symptoms were present. On the other hand, I can remember a sufficiently large number of cases having most of the classical symptoms in which a laparotomy showed other conditions.

Take for instance the case of C. H. Married some years, no children. Seen at the end of August. She had passed the period due April 2, began flowing June 13 and had flowed steadily ever since with occasionally more profuse discharge for a day or two. She had had chills and hot flashes and on several occasions severe stabbing pains in the groins lasting an hour or two. Some tissue was said to have come away. Symptoms of pregnancy present. A rather fat woman, she was first seen by me on the operating table. Previously another gentleman had passed a sound and declared the uterus empty and had felt a mass behind it. Overhastily accepting the diagnosis of extrauterine already made for me, although very probably I should have concurred no matter how carefully I had examined, I opened the abdomen and had the pleasure of coming upon a pregnant uterus, from which, returning to the vagina, I delivered a four months' dead fetus. The mass behind the uterus turned out to be two patches of exudate, each the size of one's hand, in the lower posterior segment of the uterus and the right broad ligament. Humiliating as this mistake was, — and it occurred before a large number of spectators, — I got what little consolation I could from the fact that three confrères were equally at fault. The obvious lesson is the necessity of a careful examination under ether just before the operation, which reminds me of a laparotomy for extrauterine pregnancy I was once invited to see by a leading New York operator which revealed nothing, not even a pregnant uterus. Some symptoms and a mass of feces had led him astray when he examined ten days before the operation, and he did not confirm his diagnosis under ether.

Another case of mine, Mrs. L., had this history: Amenorrhea for three months. After "feeling herself pregnant," as women say, some three weeks before I saw her she was awakened from sleep by pain in the lower abdomen so severe that she rolled on the floor in agony. (I remember that one of my earliest medical impressions was that "rolling on the floor in agony" meant in a man an appendix and in a woman a ruptured extrauterine.) This pain was accompanied by nausea. It lasted half an hour and for a few days thereafter she was very pale and fainted easily, then she began to flow a little and was still flowing when seen. The uterus was found to correspond with three months' pregnancy and there was a distinct boggy mass behind it. In three weeks more this mass had gradually dis-

* Read at a meeting of the Obstetrical Society of Boston, Oct. 20, 1903.

appeared, leaving a normal pregnancy. Of course it is possible that here was a normal pregnancy combined with extrauterine with tubal abortion. Such combined cases have recently been reported at the Obstetrical Society by Drs. Perkins and Elliot, but the chances are against it.

Or take this case to illustrate the possibility of a faulty diagnosis. Mrs. H. consulted me for a secondary sterility of four years' duration. After a few weeks' treatment of an endometritis she skipped a period. At the sixth and eighth weeks there was flowing for a few days with sharp pain in the groins. Seeing her at the eighth week, an oval movable tumor the size of a hen's egg was to be felt in Douglas' pouch with hardly any appreciable enlargement of the uterus. While a few more days' observation settled it that it was a normal pregnancy with a catarrhal tube, there was a time when I felt tempted to interfere.

Or take this case seen in consultation. Amenorrhea five weeks, then fairly sharp pain in the left ovarian region, followed for a week by the discharge daily of a small amount of old clot, culminating with fairly active expulsive pains and escape of fresh blood. The uterus was then curetted. The pathologist reported that while there was evidence of a pregnancy there was no trace of an ovum and that he could not but be suspicious from the specimens submitted that there was something going on outside of the uterus. Three weeks later there appeared in the left pelvis an oblong mass the size of a small orange and for twenty-four hours there were rythmical wave-like pains in the left pelvis, almost exactly like the pains one sometimes sees that are premonitory of the rupture of a tube. An exploratory laparotomy showed nothing but a small thin-walled rapidly growing cyst of the ovary.

Sometimes, on the other hand, when an extrauterine pregnancy is actually present, there are practically no symptoms of it or if any are present they are so slight that the case is naturally regarded as one of ordinary miscarriage. Three of my cases came to the hospital to be curetted after a so-called miscarriage, in one of them the plainly felt hematocele being regarded as a pelvic abscess by a leading gynecologist. In another the diagnosis was made by the merest accident. Miss H. (Case VIII). My house-officer telephoned me that a girl had just come in who had been flowing for a month after a miscarriage at five weeks. I told him to curette her and when I saw her next day she was doing perfectly well, so I gave her no more thought. On the day before she was to leave the hospital the house-officer told me that as she had been flowing a little more he had had the curiosity to examine her again and had felt something behind the uterus. Careful inquiry gave no history of pain or anything else except a slight flow for a month after being previously perfectly regular. I at once opened the abdomen and found it full of free blood and clots and a sac the size of a hen's egg in one tube with a rupture with old edges, though free bleeding took place on handling it, and a pelvic peritonitis apparently at least a month old.

Pelvic examination is not always of great assistance or is deceptive. Take this case: Mrs. D. (Case XII). Six weeks previously sudden severe abdominal pain, menstruation having occurred at its normal time a few days before. This was accompanied by nausea, without vomiting (present, by the way, at the time of rupture in over half of my cases); this pain lasted five minutes, leaving the patient prostrated. Two weeks later another attack with flowing for an hour. Three days later another similar attack. She was then examined by a gentleman with great experience in extrauterine pregnancy who inclined against that diagnosis as he could feel absolutely nothing and thought the case might be one of appendicitis. A week later, when under observation in the hospital, she had another attack. No tissue was passed as far as known. From the history I advised an operation. Examination under ether shows a plain enlargement of the right tube, while the left pelvis was apparently free, yet when the abdomen was open I found she had an extrauterine pregnancy on the left side — the mass on the right being only a hydrosalpinx. Even after this left tube was removed it was difficult with one's eyes shut to feel the fusiform swelling in it, which was filled with soft clot. A peritonitis had closed the distal end of the tube. A microscopic examination proved tubal pregnancy present. This condition of tubal pregnancy with closed tubes is not so very uncommon. Dr. C. H. Hare has recently reported a case of extrauterine pregnancy with double pyosalpinx. It is noteworthy that the rupture of this sac — not the tube — in the earliest days of pregnancy caused such marked and persistent symptoms, especially as the tube was not at all tightly filled with the escaped blood. This brings out another point. Some time ago, in a suspicious case at eight weeks, a physician expostulated to me that it was too early for rupture or indeed for any symptoms of an extrauterine pregnancy and I believe there is a somewhat general feeling to this effect. Leaving out the pain from the stretching of the tube which sometimes occurs very early, the dates at which rupture or tubal abortion took place in my cases was approximately as follows — sixth week, eighth, third (sac only 3 mm. long yet the abdomen full of blood), fourth, third, fourteenth, fourth, eighth, sixth, eighth, sixth, eighth. Thus in 10 of the 14 cases of which I have the data, symptoms were noticed at or before the eighth week. These figures are in close accord with those of Weindler,[1] in which 19 of 50 cases were in the first month. Cases in which symptoms occur thus early are generally tubal abortions, in which the pelvis is found filled with adherent blood clots with an enlargement very likely no larger than an almond in the tube. In several such cases I have still found blood coming drop by drop from the abdominal end of the tube, cases in which the tube had been lifted up carefully enough to exclude the hemorrhage being caused by manipulations. It is to be remembered that a very large amount of blood

[1] Arch. f. Gyn., 1900, Bd. lxi, Hft. 3.

can escape by this monotonous drop, drop, drop; fifteen drops a minute, the rate in one of my cases, gives much more than a quart a day and this hemorrhage tends to be persistent rather than otherwise unless the end of the tube gets blocked up by a peritonitis. From Weindler's study it seems evident that the menstrual period following a tubal abortion in the first month is very apt to be much more profuse than ordinary, a point worth bearing in mind in trying to explain the cause of certain cases of pelvic peritonitis in which there is a history of a single profuse menstruation without previous amenorrhea in women who usually flow a normal amount.

In these cases of early tubal abortion no trace of the fetus is likely to be found and the diagnosis can be confirmed only by the microscope, if even by that.

Should tubal abortion be deferred one can generally get a history of amenorrhea, but not always. Take this case: Mrs. C. (Case I). I found in her abdomen a fresh fetus of three and one-half months, three weeks after her first attack of pain; she had not skipped a single period she said and thought. In reality her irregular flowing due to her extrauterine pregnancy had happened to coincide in time and amount approximately with her normal menstrual flow, a possibility to be closely borne in mind in women with a history of more or less irregular menstruation.

As to the classical symptom of grave anemia, in my limited experience this is the exception.

Of my 17 cases 3 were in collapse from acute hemorrhage. In 8 free blood was present in the abdominal cavity without marked anemia. In 5 the pelvis was more or less filled with clots without free blood or any anemia. In one case who had been having symptoms for a week I found the abdomen more filled with blood and clots than in any other case I ever saw, yet her color was good and her pulse only 80 before the operation. I suppose the hemorrhage, though profuse, had been slow enough to allow new blood to be formed as fast as it leaked through the mouth of the tube. In this case the fetus was just about large enough to be seen, yet the total amount of blood lost was very large.

Another classical symptom is the escape of decidual tissue. I have come to place no reliance on this unless it is proved by the microscope. Women are more than apt to regard old blood clots as "tissue," or else when the real tissue does escape it is apt to be regarded as merely blood clot.

I suppose extrauterine pregnancies have been mistaken for almost every conceivable pathological condition in the pelvis and the abdomen too, for that matter, and vice versa, and no wonder, for a sure diagnosis is often impossible. Tubal abortions are especially difficult to diagnose, particularly those in which the hemorrhage is into a tube the distal end of which has become occluded. This is unfortunate, as tubal abortions are perhaps more frequent than cases in which the tube itself ruptures. They formed 56% of my cases.

The symptoms which seem to me of chief importance in tubal aborton are pain and anomalous escape of blood from the uterus. *Pain.* It is quite different from that of ordinary menstruation, short-lived, often stabbing and not "colicky" especially, nor anything like as severe as the agony from the rupture of a tube. This pain is often accompanied by nausea without vomiting and as a rule more or less protracted *metrorrhagia* takes place. Patients are apt not to pay much attention to this pain and think that the flow is due to only a miscarriage, and so first come under observation some weeks later, being led to seek advice on account of the pain from the pelvic peritonitis that generally results. As the abortion occurs when the enlargement of the tube can hardly be felt, and the fetus generally dies at the time of rupture of the sac, all that can be felt is often only a more or less firmly organized blood clot surrounded by exudate and exquisitely sensitive. A few times, in cases of tubal abortion, I have got dullness in the flanks from free blood, but generally the hemorrhage is small, though often persistent, and the blood is all collected in the pelvis and clotted.

The further advanced an ectopic pregnancy is the easier the diagnosis naturally becomes. If three or four months along and the patient is fortunate enough to be examined before rupture, a history such as I have outlined associated with the symptoms of pregnancy, and the presence of a pelvic tumor combined with relatively slight enlargement of the uterus, should attract the attention of the least suspicious, and fortunately the irregular flowing and the pain due to the stretching of the tube are very apt to make a woman think that if she is pregnant something must be wrong.

One little point in diagnosis is worth mentioning. It used to be taught that ectopic pregnancies are far more apt to occur in multiparæ after a protracted secondary sterility. This is not always strikingly so; 41% of my cases were primiparæ.

As to *treatment* there are five questions that have occurred to me and it is with the hope of eliciting a discussion of them that I have been led to prepare this paper:

1. Should a case seen immediately after rupture — in collapse and acute and profound anemia — be operated upon at once, running the risk of operative shock proving the last straw in the scales of life and death, or should we wait until the patient has rallied somewhat from the shock of rupture, aided by strychnia or alcohol and salt infusion and more especially adrenalin?

I recognize that the waiting policy has very able advocates who have had greater experience than I have. One must resist the temptation to dogmatize, but personally I feel that I should prefer to operate at once, no matter how grave the condition, or rather, the graver the condition the more prompt would be my attempt to reach the bleeding point, for while twelve hours or so *may* give a patient some hope of recovery from the primary shock, we have no certainty but that

meanwhile blood may be coming out of the torn tube quite as rapidly as we can introduce salt solution under the breasts — nay, even our efforts to increase the volume of blood in circulation are very likely only increasing the quantity available for pumping out into the abdominal cavity and at the same time replacing the lost blood with a fluid of low coagulability. In a recent discussion on this matter an eminent gentleman said it was his experience that cases of accident operated upon in a condition of shock generally died. This is, of course, true and nobody would dream of operating on a recent tubal rupture if — and the whole point of the matter lies in that " if " — if we could be sure that there was meanwhile no hemorrhage going on into the abdominal cavity. I always understood it was a primary surgical rule to find your bleeding point and then wait if thought best. Common experience shows how marvelously patients recover after bleeding has once stopped. One advocate of the waiting treatment expresses scepticism as to women bleeding to death from the rupture of a tube, saying that the hemorrhage will stop of itself when the woman is sufficiently exsanguinated. Within six months I have heard of four cases of death from such acute hemorrhage occurring within a few miles of Boston. As to the shock of an operation taking away the woman's one chance, I do not think its risk is comparable with the risk that she will bleed to death. It is well enough in a grave case to say " wait, and if she loses ground we will then operate," but if you do so, when that ground is lost her chances have not improved any. As to the argument that one does not like to operate upon a dying woman, I cannot but feel that to let her die without an attempt to relieve her does not bring any great glory to surgery. My rule is to get ready for operation, stimulating the patient meanwhile. If she reacts and holds her own, wait, but at the first sign of losing ground operate. If no reaction, operate and give her her one chance.

Three only of my cases were in collapse when operated upon. One of the two that I lost, Hennesey (Case VI), was thought to be dead in the carriage on the way to the hospital. She responded a very little to stimulation at first, but by the time I could reach her she had begun to fail again and was almost pulseless when the ether was started. She was dead an hour after the twenty-minute operation was completed. She lost no blood from the operation and there was very little handling of the intestines. Bleeding from the torn tube was steady and free, considering how exsanguinated she was. As death from acute anemia was otherwise inevitable in the near future, I feel that reaching the bleeding point gave her her one chance in a thousand and have never regretted that I opened her abdomen.

The other fatal case was a primipara, seen in consultation with Dr. Boland, two hours after the rupture at six weeks. Within an hour of the time she was seen I opened her abdomen at the Carney Hospital, and found it full of blood with free hemorrhage going on. She died on the third day, apparently from exhaustion. I afterwards found that she had been having attacks of heart failure for some months, and it was one of these combined with the profound anemia that caused her death. She was in a state of fairly deep shock when operated upon and was growing worse all the time. To sit still and wait for reaction in such a case seems to me sacrificing most of one's chances.

The third case operated upon in collapse (Case IX) seemed in quite as bad condition as the first, and coming within a week of it gave me a good chance to compare the two. In my notes I read " seems much better after the operation, as now a faint flutter can sometimes be obtained at the wrist." She certainly seemed a pretty hopeless case, yet she did perfectly well, the pulse dropping to 140 within twelve hours. Bleeding was found to be going on freely from a vessel large enough to have practically filled the abdomen in the three hours between rupture and the operation and I think by the time the vessel was tied she had lost about all the blood she could afford. With a case like this in mind, I confess to a good deal of scepticism about waiting for a woman to recover from shock if meanwhile she is going to bleed to death. I do not deny that when a woman is not blanched and percussion does not reveal much free blood it may not be well to give her a chance to react before interfering, but I do wish to protest against sitting with folded hands with a patient showing evidences of acute anemia.

2. The second question that occurs to me is — with a diagnosis of probable unruptured extra-uterine pregnancy is it better to operate at once or wait until the diagnosis is certain? I should feel that a reasonable probability implies an immediate operation. Certainty generally comes only with rupture, which is often not considerate enough to give much warning. One of my worst cases, who was being "watched" by another man, was awakened from sleep by the rupture and came very near dying before she could be operated upon.

3. The third question is — given a tubal abortion, say a month or so before the patient is seen, is it better to operate, supposing one can feel a mass, or to allow nature to take care of it? Nature will, I think, generally take care of it more or less sufficiently after a longer or shorter period of pelvic peritonitis with pain if nothing worse, but it seems to me infinitely more surgical and certain to clear out the pelvis in such cases, remove the old clots, break up the adhesions, patch up the tube by resecting portions of it or by splitting it and removing clots from its cavity and sewing it up again. The whole story seems contained in the observations of a recent writer who compared some three hundred cases treated by operation with an equal number treated expectantly. The mortality was in both cases practically the same, but under operative treatment convalescence averaged eight weeks, while under expectant treatment it averaged eight months.

4. The fourth question connected with the treatment is the old one — below or above? Tubal

pregnancies, of course, are accessible from below. Recently Kablukoff removed a seven months' fetus through an opening in the posterior or anterior vaginal wall, leaving the placenta to discharge later. Of course the men who have done enough vaginal celiotomies to be expert thereat may prefer that route in many cases. I am not one of them, nor likely to become so. A single experience satisfied me. I was once asked to drain a pelvic abscess following a miscarriage. On incising the posterior cul de sac I came upon free blood and in my attempts to deliver through that vaginal wound an adherent tubal fetation I stirred up enough more hemorrhage to make me glad enough when I was finally able to control it by stuffing the pelvis full of gauze and then go in after the bleeding point by the abdomen as rapidly as I could with the patient of course quite unprepared for a laparotomy. An incision in the posterior vaginal wall may, however, be useful to settle doubts as to diagnosis, but it is well to be prepared for an abdominal operation. In some cases it might be well to attempt to control further hemorrhage by clamps from below, delaying removal of the tube by the abdominal route until the patient shall have recovered from shock and acute anemia.

5. I have had no experience with extrauterine pregnancies at full term. The treatment of the placenta in such cases is the fifth question that has occurred to me and I think it is about as difficult a one as the surgeon ever has to meet. Whether it is better to attempt to remove it with the probability of a furious and very possibly uncontrollable hemorrhage, or to stitch the sac to the abdominal wound and allow the placenta to come away gradually with the still great danger of hemorrhage when it separates or sepsis if it sloughs, with conditions very good for a hernia in the future, is certainly no easy problem to solve. Of course if the main blood supply to the placental seat can be found and tied off, the problem becomes much easier, but this is by no means easy. In the only case of the kind I ever saw the sac was stitched to the abdominal wall and very tightly packed with iodoform gauze and in a few days the placenta came away without hemorrhage. Men who have removed the placenta in cases where the child was alive at the time of operation describe it as a nightmare.

The only other point I wish to touch upon is the after history of cases of extrauterine pregnancy. What hope can we give a woman that an extrauterine pregnancy will ever be followed by a normal one? I should say very great hope. My sixth case gave birth to a child fifteen months after I had operated upon her for a typical extrauterine rupture. I came across a woman only the other day four months advanced in a normal pregnancy upon whom Dr. E. Reynolds operated last year for an extrauterine. Prochowik found that a normal pregnancy followed an extrauterine in about 40 out of 80 cases. Curiously enough, the proportion of subsequent normal pregnancies was practically the same whether the cases were operated upon or not. A normal pregnancy may even intervene between two extrauterine ones. I have found two such cases. I think every one is now agreed as to the advisability in young women in leaving at least a part of one ovary in mutilating operations upon the appendages for physiological reasons. This is never more true than in cases of extrauterine pregnancy occurring in primiparæ. In view of the many children following an extrauterine pregnancy it seems to me almost criminal to deprive a woman of the chance of maternity. The old teaching was to remove both ovaries, lest she have another extrauterine pregnancy; my view would be to remove as little as possible, in the hope that she may become normally pregnant. It has always been my hope in a suitable case of unruptured tubal pregnancy to be able to split the tube, remove the sac and products of conception, stitch up the tube and drop it back again. Only the other day I determined to do it in such a case at three months. Unfortunately she fell into another man's hands at the last moment, who removed the tube and ovary.

On the other hand, the possibility of a second extrauterine must be borne in mind. I reported three years ago [2] a case of repeated extrauterine pregnancy on whom I had operated twice. I have since then had an even more striking case.

Mrs. R. 11-para. In December, 1901, I operated for a tubal abortion at one month. The diagnosis was confirmed by the microscope. In May, 1902, she had an attack of pain on the other side after two months' amenorrhea. Irregular flowings took place and the history in brief was a typical one. I first saw her three weeks after the rupture and watched the mass slowly disappear without operation.

In September, 1903, I operated again for a tubal rupture at three months or a little less. Though the fetus was not found, the diagnosis was again confirmed microscopically. Thus within the space of three years she had three practically certain extrauterine pregnancies.

I am afraid I have left the question of diagnosis in rather an unsatisfactory condition. I cannot help it, as my own ideas on the subject are very hazy. In many cases a positive diagnosis is out of the question, as it is for that matter in many other abdominal conditions. Often one will have at best but a feeling from the history that in spite of scanty tactile evidence there is trouble in the tube and I am certain that in such cases the 'let alone and wait" policy will never give as satisfactory results as operative interference. If you do not find an extrauterine pregnancy you will probably find some trouble that will be the better for plastic work, — building a new osteum, for instance, if the tube be closed by catarrhal inflammation, or an ovary needs partial resection, or some adhesions should be broken up, or something, — while if you find nothing I do not think that a competent man should be blamed if in view of the possibilities of a neglected extrauterine pregnancy he insists in setting his suspicions at rest one way or the other.

TYPHOID FEVER IN CHILDREN.*

BY ADOLF BAGINSKY, M.D., BERLIN, GERMANY,

Professor of Children's Diseases, University of Berlin; Director of "Kaiser und Kaiserin Friedrich Kinderkrankenhaus."

(Concluded from Vol. CXLIX, No. 27, p. 725.)

INDIVIDUAL SYMPTOMS.

Nervous System. — The nervous symptoms of children ill of typhoid are not usually so pronounced as in the case of adults, but individual cases differ greatly from each other. The majority of children are from the beginning in bad humor and whine when disturbed, remaining in this condition throughout the sickness except when the peevishness gives place to a condition of apathy and stupor. Other children are restless from the beginning, tossing about and moaning, the older children complaining of decided headache; these become very apathetic and even fall into a light stupor from which, however, they can be awakened by being taken up, questioned, etc. Still others show an intense restlessness from the very first, crying, screaming and tossing about. During the progress of the disease the mind becomes more and more dull; the little patients become delirious, scream continually, have a tendency to spring out of bed, forget their surroundings and often in great excitement fall back into a deep stupor with which the former symptoms alternate. In some cases I have seen the deepest stupor which lasted for days, in one case even for weeks, accompanied by grinding of teeth and a general relaxed condition of all the voluntary muscles, the child during the entire time scarcely uttering a sound. I have seen complete reduction of the fever besides violent delirium follow the administration of large doses of salicylate of sodium. I cannot remember ever having seen general convulsions in connection with typhoid fever of children, although such cases are recorded. In a case mentioned by Lewy, in a child fifteen months old, laryngismus, rigidity of the neck, general convulsions and anesthesia developed during the course of the illness. The case was probably a complicated affection of the central nervous system. Meningitis is also an occasional complication of typhoid and I have observed one such case which, however, ended fatally. Other cases have been described by Wentworth [26] and Zorm,[27] in which they found the bacillus in the meningitis pus of the spinal fluid. Henoch has observed similar cerebral disturbances, and has called attention to the relative frequency of aphasia in typhoid. The most conspicuous of all the disturbances of the special senses is that of hearing.

Organs of Respiration. — The organs of respiration are always affected in typhoid of children, sometimes very early in the sickness. Lewy's above-mentioned case developed such severe laryngeal symptoms that the stenosis required tracheotomy. Catarrhal affections of the bronchial tubes accompanied by cough so frequently appear in the course of the disease that they may be considered regular symptoms. In the more severe cases, however, atelectasis of the lungs and catarrhal pneumonia may develop out of these apparently insignificant symptoms, complicating the course of the disease and greatly diminishing the chances of recovery. The physical signs (räles, dullness, diminished bronchial breathing) show the condition of the respiratory organs.

Organs of Circulation — Blood. — The action of the heart and pulse have already been described, but it is important to consider the condition of the blood, which, while not always the same and characteristic, usually shows a certain degree of leucocytosis. I have found a proportion of 1:650–1,200 between the leucocytes and erythrocytes. The number of eosinophile cells was small, from 0.5%–0.8%. The amount of hemoglobin varies from 24% to 52%. The foregoing statement is confirmed by the investigations of Naegeli,[28] Becker,[29] Courmont and Barfarow,[30] and they further state that during the period of high fever there exists a constant decrease of the number of neutrophile cells and lymphocytes. The eosine cells disappear almost completely during the height of the fever and only return shortly before the fever becomes normal or even later. I have not been able to find any certain prognostic sign from the condition of the blood, but the blood condition is particularly valuable for differential diagnosis when other signs are absent. The specific agglutinating ability of the blood for new cultures of typhoid bacilli exists in children the same as in adults and is therefore valuable for diagnosis (Widal's reaction), but it is not an absolutely positive sign. This will be more fully considered under the heading "Diagnosis."

Organs of Digestion. — The abnormalities of the digestive tract show themselves even in the lips, tongue and mucous membrane of the mouth. The entire mucous membrane of the mouth is reddened and has a color darker than normal; the lips are dry, the tongue somewhat moist with a gray coating in the middle, red edges and point. If the child remains conscious the picture changes a little during the course of the illness; but if he becomes unconscious and delirious and lies with the mouth open the lips become cracked and bleed easily. A dirty gray coating is formed upon the mucous membrane of the mouth near the edges of the teeth, the tongue looking as if it were smoke-dried, shiny and pointed. The mouth and tongue are also the seat of small ulcers with yellowish coating and red edges, but which is not real aphthæ. Among the real complications we shall have to mention stomatitis and noma. The pharyngeal mucous membrane is reddened and dry; the tonsils are generally enlarged and the seat of follicular inflammation.

The fact should never be lost sight of that an unusually protracted angina with very high fever may be the only early symptom of typhoid. Wagner and Roemheld [31] describe another form of pharyngitis in which small flat ulcers are formed in the beginning and during the course of the disease but without involving the tonsils, and Cadet de Cassicourt pretends to have seen a catarrhal pseudomembranous and ulcerative form of tonsilitis in this connection. I can confirm the theory that the disease is introduced into the system through the angina. Vomiting is frequently observed in the beginning and during the course of the disease, coming on without apparent cause. I have already spoken of bloody vomiting. In the early days of the illness the abdomen is but little swollen, but it becomes more so as the case progresses, and often develops severe tympanites. The feeling of gurgling in the ileocecal region is not very pronounced, but this part of the abdomen and also along the course of the colon is painful on slight pressure and the spleen is often very sensitive. In children diarrhea may be lacking during the entire course of the disease, or particularly in the beginning, a rather severe constipation may be present, but this gives way later to the well-known and often severe typhoid diarrhea. The spleen, which continues to enlarge till the fever reaches its height, may in the majority of cases be easily palpated below the border of the ribs and when not hindered by tympanites the tumors may be proved by percussion.

Urinary Organs. — The urine has a high specific gravity, is scanty and according to Eckert, Hagenbach and Geier rather frequently contains albumen. In case with high fever I have sometimes found this continuing for a week or two. This is usually accompanied by the presence of cast-off and broken-down epithelial cells and casts. It is questionable if we have a real nephritis in these cases, but a nephritis may be a complication and an attempt has been made to fix a renal form of typhoid (Amat, Weil). Ehrlich's diazo reaction is important in considering the excretion of the typhoid bacillus with the urine, as it is a valuable test, particularly during the height of the fever. Since I have paid more attention to this reaction I have not found it absent in a single case, and I therefore consider it a helpful diagnostic aid though not absolutely certain. In the beginning of the illness the excretion of urea is often but not always increased. In the majority of cases also a strong indican reaction is present. The chlorides are diminished, but the excretion of the inorganic salts shows nothing characteristic (Jacubowitsch).

Skin. — The most noticeable appearance in the skin of typhoid patients is the roseola. It appears scantily but is rarely lacking, and if one look closely one is almost sure to find the small slightly elevated spots which are scarcely as large as a lentil. In exceptional cases a very abundant rash appears which may almost be mistaken for an accidental exanthem. In relatively numerous cases the roseola reappears even after the fever has disappeared and is usually followed by a relapse. I have never seen the exanthem described by Rendinger,[32] which simulates measles and scarlet fever, neither have I observed the desquamation which he and Jacobi [33] describe. Miliary rash appears on the skin of children very easily and often, and therefore frequently accompanies typhoid. Considering the inclination of severely sick children to soil themselves, deficient nursing may easily be accountable for severe erythema and eczema. However, these complications are not so common as one would expect, and decubitus is really the exception, and when it does occur it appears mostly as a necrosis of the skin over the coccyx. Hemorrhage of the skin occurs but rarely and then in connection with a hemorrhagic diathesis or blood dissolution. Occasionally hydrops of the skin accompanies typhoid with or without albuminuria, or it may appear as a secondary symptom.

[31] Roemheld (Vierordts' Klinik): Jahrb. f. Kinderheilk, Bd. 48, p. 207.

ABNORMALITIES.

Abortive form. — The most insignificant and shortest forms of typhoid often occur in children and are but a weak reflex of the typical illness. These cases are characterized by slight gastric disturbances, somewhat typical typhoid tongue, moderate fever with evening exacerbations and positive diazo and Widal reaction; but still more significant is the occurrence of other more serious cases at the same time.

Relapse. — A relapse is characterized by the reappearance of the fever some days after it has disappeared, the return of the typical fever curve and of the other described symptoms. A relapse may continue as long as the first attack and, as I have recently observed, even longer. They are very disagreeable. I have several times seen such cases with two long and obstinate relapses, seriously exhausting the patient, but ending in recovery, — one of them after a critical sudden fall of the temperature. Children are unquestionably more predisposed to relapses than adults and Montmollin [34] has observed that girls are more liable to this complication than boys. These relapses may of course end fatally. The nervous forms of the fever which I have described and which are accompanied by vomiting, irregular pulse, grinding of the teeth, loud crying and very deep stupor may cause extremely great difficulty in diagnosis. These cases simulate tubercular meningitis very closely and errors can only be avoided by the most careful examination of the spleen, the appearance of the roseola, the condition of the tongue, observation of the fever curve and finally the knowledge of an epidemic or the proof of the typhoid bacillus and positive Widal reaction. The following is a case in point:

A pale, fairly well nourished, but very sick-looking boy of two and one-half years was received into the hospital with a temperature of 40.6° C. (105+° F.). During the

[32] Rendinger: Rev. de Méd., 1900, No. 2.
[33] Jacobi: Pediatrics, viii.
[34] G. de Montmollin: Inaug. Diss. Neuchâtel, 1885.

first days of the illness symptoms similar to typhoid appeared with the exception of a slight stiffness of the neck. Suddenly, however, great restlessness and jactitation were observed, followed by loud screaming, trembling in all the extremities and a convulsive sucking motion of the mouth. The pupils reacted to light. Cyanosis and dyspnea now appeared. All these symptoms were more marked on the following day, particularly the spasmodic contraction of the muscles. Violent screaming became more frequent. The child became weaker and weaker and finally died on the ninth day after coming to the hospital, but real convulsions never developed. It is noteworthy that on the first days both ears ulcerated after paracentesis. The paracentesis did not at all lessen the nervous symptoms. Aside from the severe congestion of the blood vessels of the pia mater the brain showed scarcely anything abnormal and only a small amount of serous secretion was found in the tympanic cavity. The spleen was greatly enlarged and moderate-sized typhoid ulcers were found in the intestine. The severe nervous symptoms were undoubtedly due to the severity of the general infection.

COMPLICATIONS AND SEQUELÆ.

The frequent complications of the respiratory organs have already been spoken of. Nearly all recent investigations prove that the typhoid bacillus is the cause of the complications ,particularly the frequently observed fibrous and catarrhal forms of pneumonia and atelectasis of the lungs. Severe acute diffuse laryngitis (Lewy, Schuster[35]), largnygeal perichondritis with abscesses, ulceration of the larynx and threatening acute edema of the glottis do not belong to the complications of typhoid. Pleurisy and empyema occur in typhoid relatively seldom, at any rate more rarely than in scarlet fever. Fernet, Achard, Fraenkel and others have proved the bacillus in the sero-fibrinous exudate. Single cases of gangrene of the lung are recorded. On the part of the heart adynamic conditions are less to be feared on the part of children than in adults; however, they do occur in obstinate and severe cases and become particularly dangerous to such children as continually refuse to take nourishment. They may be easily recognized by the slight coolness of the extremities, weak, diminished or rapid and irregular heart action and by a dullness of the heart sounds, particularly the disappearance of the aortic second sound. These deserve careful attention, particularly if on account of the fever we desire to give antipyretic remedies. I have not observed so great a tendency to bleeding in children as in adults, except early in the sickness nosebleed is somewhat frequent; but this rarely becomes serious. However, when the blood is swallowed it may be vomited. Montmollin records a case of embolus of the left brachial artery in a girl eight years old, sick of typhoid, and single cases of pericarditis and endocarditis complicating the disease. I have seen thrombosis of the saphenous vein in connection with typhoid beside severe decubitus in a girl fourteen years old. These, however, are rare cases, Certain anomalies of the digestive organs are occasionally observed in the course of typhoid. Parotitis and noma may occur in this connection and while they are serious fortunately they are rare. Parotitis appears as a swelling on the side of the face in front of the ear and sometimes, but not always, goes on to suppuration. As a rule noma is fatal, but I have had the good fortune to see one such case recover.[36] The affection generally begins on the gums or the mucous membrane of the lips as a dirty yellow or gray-green coating simulating diphtheria. This gradually spreads and advances into the mucous membrane of the cheek which decays into a fetid mass surrounded by a dark infiltrated border. The destruction of tissue in the progress of the disease is enormous and the sight of the child, who spreads a pestilential fetor to a great distance, is disgusting.

Bloody diarrhea is seldom observed in typhoid of children. It does occur, however, in older children, and may become serious on account of the loss of strength caused by it. I have seen a boy six years old recover from typhoid fever complicated by severe nosebleed, intestinal hemorrhage and petechiæ of the skin. In another case the illness, accompanied by high fever and severe general nervous symptoms, came to a crisis with an intestinal hemorrhage. The temperature suddenly dropped to 36° C. (96.8° F.) and from that moment convalesence began. In another case, ending fatally, a boy nine years old developed purulent diarrhea. The autopsy showed very extensive typhoid ulcers of the colon as well as of the small intestine. Peritonitis caused by the perforation of an intestinal ulcer is rare, although Montmollin records 7 such cases of which 3 recovered. In 117 cases mentioned by Roemheld 3 died of perforative peritonitis. I have had the opportunity of seeing two such cases, a boy six years old and a girl of ten. Both cases terminated fatally. The latter case had the following history:

The girl ten years old had been severely ill for fourteen days and was brought to the hospital in a state of collapse and delirium. Everything pointed to severe typhoid fever — stupor, temperature 39–40° C. (102.2°–104° F.), weak pulse, enlarged spleen, slight diarrhea and Widal reaction, 1.60 dilution positive after two and one-half hours. On the third day after coming into the hospital she had a sudden chill and became collapsed and pulseless. Nose and tongue were cold, stools frequent and spontaneous. In spite of the use of all the known internal and external stimulants in addition to the injection of physiological salt solution, the case progressed badly. The abdomen appeared flat, the abdominal walls on their external border seemed stretched and intensely painful on the slightest pressure, area of liver dullness was enlarged. The collapse increased, the eyes became sunken, the abdomen was hard, contracted and painful on the borders under palpation. Vomiting developed and the spontaneous stools were thin, green and foul smelling. The child died the fifth day after coming into the hospital. The autopsy showed a very large number of deep typhoid ulcers, two of which had perforated the walls of the jejunum and ileum. The perforations were scarcely larger than a poppy seed or a lentil, the intestine was covered with a sticky pus and a diffuse peritonitis had developed.

Acute otitis media in the course of typhoid fever is a serious complication and leads to grave cerebral symptoms — dullness, stupor, delirium, and particularly the continued high fever. With the spontaneous discharge of pus or after paracentesis the symptoms soon disappear and the course of the illness becomes more favorable.

[36] Archiv f. Kinderheilk, Bd. 13, p. 302 u. 402.

Among the further sequelæ belonging to the disturbances of the cerebral function are mania or melancholia, with chorea, tremor, paralysis of the extremities as a result of peripheral polyneuritis (Judson S. Bury [37]), followed by atrophy and diminished reaction, and aphasia. The aphasia usually appears in connection with an adynamic disturbance of the heart as described above. In these cases, as a rule, the motor form of aphasia is observed and the intended speech is indistinctly articulated. Sensory aphasic disturbances are not altogether unknown and other psychical changes sometimes take place. Deafness often occurs as a result of chronic otorrhea and sometimes without it. Purulent joint inflammation, diphtheritic coating of the vulva of little girls, skin diseases, as boils, abscesses and erythema, are also among the less commonly observed complications and sequelæ of typhoid fever. I have been able to cultivate the typhoid bacillus from the furuncles of an eight year old girl convalescing from the fever. Erysipelas is a frequent sequel and develops as in Rheiner's case from the pure typhoid bacillus or from the erysipelas coccus (Escherich and Fischl). As further sequelæ periostitis, ending in necrosis of the bones, has been described (Freund), total necrosis of one extremity (Drevitt [38]), and the already mentioned case of hydrops (Henoch). Finally, typhoid fever frequently occurs in connection with the acute exanthematous diseases or other infectious processes, as scarlet fever, measles, whooping-cough, diphtheria or membranous croup. I saw in the child of a physician during the course of two months, whooping-cough, broncho-pneumonia, typhoid fever and measles, from all of which the child recovered. With three children in one family whooping-cough complicated severe typhoid. Malaria occurs with typhoid and Russian physicians particularly (Bistrow) point to this peculiar combination. In these cases described by Bristow the abnormal fever curve could only be brought to the more regular form by the administration of large doses of quinine.

DIAGNOSIS.

The diagnosis of typhoid fever, which is difficult in the beginning, will become easy as the case develops by making continued observations of the fever curve and by a process of exclusion. The chief diagnostic signs are the general appearance of the patient, the characteristic remittent fever, gastric disturbance, diarrhea, condition of the tongue, enlargement of the spleen, roseola and the diazo reaction. The diazo reaction is explained as follows:

Mix an equal quantity of urine and sulphonitic acid solution (sulphonitic acid 5.0; hydrochloric acid, 50; distilled water, 1,000) and add 2–3 gtt. of a solution of sodium nitrite (sodium nitrite, 0.5; distilled water, 100). Add to the above mixture ½% of ammoniac. The whole must be well shaken in a test tube and the color of the rising foam observed, and if it appears dark red the reaction is positive. The sodium nitrite solution must develop a brown vapor when mixed with a few drops of a concentrated hydrochloric acid. This test must be applied from time to time and when necessary a fresh solution be prepared.

The Gruber-Widal reaction is usually but not always another very useful help in diagnosis. I have, however, several times observed that all clinical symptoms pointed to typhoid when this reaction was lacking; nevertheless the diagnosis of typhoid fever has been made essentially easier by the introduction of this test, which it should not be forgotten is a result of Pfeiffer's discoveries. The reaction takes place to a certain extent with normal blood serum, but it is more quickly and certainly performed with typhoid serum, and above all it occurs in high dilutions. It rests upon the common observation that blood serum in a dilution of 1:60 when brought into contact with a drop of a bouillon typhoid culture twelve hours old brings about an agglutination of the bacilli which may be examined microscopically. The test is made in the following manner:

From a small puncture of the child's finger remove a little blood and let it set in a short test tube. Mix one part of this blood serum with 50–60 parts of a very opaque typhoid culture which has been in the thermostat at 37° C. (98½° F.) for six to eight hours. We then examine the mixture microscopically by means of a hanging drop and observe if the naturally lively bacilli remain quiet and form into balls. In case this fails the experiment is repeated in fifteen minutes to one hour, always leaving the preparation in the incubator. The reaction is not considered satisfactory if a large number of bacilli remain movable and single. Microscopically the agglutination can be made certain. If we leave the mixture of diluted blood serum with the typhoid culture in the incubator the bouillon shows a precipitate while the liquid has become clear.

The differential diagnosis between typhoid fever and miliary tuberculosis is often difficult and in many cases we must wait for the appearance of meningitic symptoms, irregular pulse, vomiting, constipation and finally general convulsions before we can be sure we have the latter condition. Among the feverish illnesses, pneumonia, particually in the early stage, may be mistaken for typhoid, but in this case repeated blood examination will undoubtedly greatly assist in differentiating the two diseases, as in pneumonia we usually have an increase of the leucocytes while in typhoid they exist in diminished numbers. Finally, frequent physical examination of the lungs will reveal the pneumonic center and prevent further error.

PROGNOSIS.

The prognosis of typhoid fever of children is as a rule favorable. I have observed 88 cases in the hospital, of which 5 died, a mortality of 5.6%. In my private practice I have been more successful. This corresponds pretty closely with the experience of others. The majority of authors record a mortality of 7.8% (Steffen, 6.8%; Henoch, 7.5%; Wolfferg, 4.7%; Barbier and Herrenseckmidt 8.6 and later 4.3%; Cadet, de Gassécourt, 8%; Variot and Devé, 10%; Comby, 7.26%), but there are more fatal epidemics, as Guinon reports a small series of cases with a

[37] Judson S. Bury: The Medical Chronicle, June, 1892.
[38] Drevitt: Lancet, 1890.

mortality of 17.34%. This depends upon the malignancy of the infection. The prognosis depends very materially upon the treatment and the period at which it is begun. There can scarcely be a doubt that moderate antipyretic treatment with a consideration of the complications improves very considerably the prognosis. It is interesting to compare the results in different institutions, but experience in the hospitals of Lyon, Basel, Paris and other cities proves that judicious application of the cold water treatment has reduced the death rate from 15% to 3.5%. Of course the treatment must be used intelligently. Proper diet and careful nourishment decide the prognosis in many cases as errors in diet and insufficient nourishment often affect the outcome badly. Cleansing the patient and everything coming in contact with him is of the utmost importance.

The prognosis of typhoid is affected seriously when pneumonia, parotitis or other infectious disease or even noma complicate the disease. One of my patients who died had suffered shortly before from chorea with endocarditis. In cases complicated by cerebral disturbances, deep coma, severe delirium, jactitation, severe diarrhea, the chances of recovery are very much reduced. I have had a patient four years old who died from severe diarrhea and a slow but progressive paralysis of the heart undoubtedly brought about by an error in diet; and in the case of the before mentioned boy with purulent diarrhea, the fatal intestinal affection was probably from the same cause. We have very little to fear from a decubitus in the typhoid of children.

TREATMENT.

In even the light epidemics of typhoid fever the strictest prophylaxis must be exercised. Children should be protected from the use of infected water and food, particularly milk, and during times of danger they should be provided with drink which has been boiled and afterward cooled. It is of the greatest importance to disinfect everything coming in contact with the patient,—the washing, playthings, books, etc., — for only in this way is it possible to prevent the spread of the disease in the family. Adults who have to care for the patients must be careful to cleanse the hands. As Koch has recently very properly pointed out the slightly ill are very often the careless transmitters of the disease to others. Children are often seen who complain of nothing but diarrhea, but who later develop fever and die. These are certainly often the source of typhoid contagion and the excreta of all such cases should be carefully disinfected. Very few diseases develop more urgent therapeutic problems than typhoid fever, and the physician's resources are often severely taxed; but these are cases where his services are of decided value. The knowledge that the typhoid bacillus is the cause of the disease brings to the front the question of a specific antibacteria therapy. Experiments have been made in this department of immunisation therapeutics by means of serum or the treatment by the metabolic processes of foreign bacteria,[39] but for the practical purposes the results have not been satisfactory. For some time calomel has been a much lauded drug as a typhoid abortive remedy and on account of the tolerance of children for this medicine no mistake will be made if we use it in the early stages of the sickness. We may prescribe it in doses of 0.03 to 0.05 ($\frac{1}{2}$ to $\frac{3}{4}$+ gr.) every half hour or every two hours, provided the patient is still in the early stage of the fever. Unfortunately experience has not borne out the early reputation of the drug in this connection, and this is true in a higher degree of naphthaline, sodium benzoate, iodoform, benzo-naphthol, etc. With the knowledge that continued high fever plays an important part in the danger of typhoid the antipyretic method of treatment has the same importance for children as for adults and we have therefore in both classes of patients the two great groups of remedies: (1) The bath and the cold pack. (2) The internal administration of antipyretics, or quinine, salicylate of sodium, antipyrine, antifebrine, phenacetine, lactophenine and others. While we acknowledge the general principles of the above outline of treatment, we object to its routine application. In adults, energetic antipyretics are contraindicated under certain circumstances, *e. g.*, threatening heart paralysis, complications of the organs of respiration (pneumonia, atelectasis) and certain disturbances of the digestive apparatus (diarrhea, dysentery). These contraindications apply in a high degree to children, for we must take into consideration certain physiological peculiarities possessed by them. First of all the well known fact must be borne in mind that the sensory nerves of the skin are very irritable, and also that the reflex irritability of the respiratory centers when cold is suddenly applied to the skin is very great. These peculiarities, which are of advantage in atelectasis, capillary bronchitis and catarrhal pneumonia, are a disadvantage under other circumstances. Rapid, repeated and long-continued cooling of the skin is dangerous to children on account of the risk of overtiring the respiratory centers, but also on account of the danger that this irritation may affect other centers, particularly the motor center. It is still more important to consider the mechanical effect of the external application of cold on the heart through the contraction of the small vessels of the skin and the corresponding dilatation of the internal blood vessels. The weakened heart action brought about by insufficient nourishment or pathological changes of the heart muscle may easily lead to fatigue and heart paralysis. A similar effect may also be brought about by such remedies as directly affect the heart muscle as, *e. g.*, salicylate of sodium and most of the other antipyretics. The rapid radiation of heat from the relatively large surface of the body may easily lead to unpleasant complications. Owing to these peculiarities, therefore, the antipyretic treatment of children is like a two-edged sword,

[39] Versuche von Rumpf und Fraenkel: Deutsche med. Wochenschrift, 1888, No. 41, mit abgetöteten Culturen von B. pyocyaneus.

requiring careful use. Other factors must be taken into consideration. It must be remembered that the antitoxin which neutralizes the toxines circulating in the blood are formed under the influence of the fever; therefore, a forced cooling of the body, instead of assisting the patient, simply keeps down the high fever, prevents the elimination of toxines and does the patient injury. Each case must, however, be dealt with according to its individual needs.

Children with typhoid cannot stand very cold baths. The enormous excitement caused by the application of cold to children counterbalances the advantage we might otherwise expect to gain and dangerous collapse may occur during or afterward. The slowly cooled bath holds the fever down longer than the cold bath; therefore it is best to begin with water not lower than 25° C. and gradually reduce it to 22° C. or 20° C. (77° F.–68°F.). The child remains in the bath about five to ten minutes or till a slight feeling of chilliness appears. Before each bath a dessertspoonful of Hungarian or port wine is given. The younger the child the more careful we must be in the application of the cold water treatment. Children twelve to fourteen years old bear water of 20° C. from the beginning. The permanent luke-warm bath after the method of Riess is apparently to be recommended. By this method the child is laid upon a sheet which is spread out in the tub beneath the surface of the water and there he remains according to the height of the fever for hours or days. Children bear the cold pack very well and it may properly replace the cold bath. By this method a moderately moist sheet is spread upon a woolen blanket and the child is quickly rolled in them and allowed to remain there ten minutes. This procedure is repeated three times in quick succession, after which the patient is rubbed dry and placed in bed under a light covering. The attempt to keep the temperature almost to the normal by means of the cool bath or pack every two hours is decidedly objectionable and no one knows what mischief may be caused by it. A certain degree of fever belongs to the sickness, but excessive temperature must be treated and if possible kept below 40° C. (104° F.), but accompanying circumstances must be considered. I have never ordered more than two or three baths a day for children. If possible, limit the antipyretic treatment to the use of external means for reasons which I have more fully set forth in my brochure on antipyretics [40] Internal antipyretics are used very unwillingly, but among these preference is given to quinine, but the dose must be sufficiently large. For a child one to two years old, I use at night, within one or two hours, 0.5 to 1 gm. (8–15½ gr.). As a rule we get an excellent effect provided the stomach retains the medicine, — otherwise the same quantity is administered per rectum. A. Jacobi says he has had good success with subcutaneous injections of quinine carbamide, but I have had no experience with it. Salicylate of sodium, phenacetine and antipyrine may be very cautiously used and we may perhaps give aspirin (or pyramidon, 0.1–0.15) in doses of 0.5 gm. (8¼ gr.) two to three times a day, but all these remedies depress the action of the heart and may become dangerous to weakened children. I have seen such a result follow the rapid reduction of temperature by aspirin.

Under constant control of the thermometer, antipyretics may be administred in the above manner, but there still remains much more to do for the patient besides the reduction of the fever.[41]

Success in the treatment of typhoid depends largely upon the proper nursing of the patient. Bouillon, wine, yolk of egg with water and wine (1 yolk egg, 2 teaspoonfuls wine, 5 teaspoonfuls water), milk, cornstarch preparations, as encosine, eulactol, peptone preparations, plasmon and somatose, are among the foods that may be given. The intervals of feeding should be short, ¼–½ hour, each feeding to consist of 1 to 2 teaspoonfuls. All solid food is forbidden. For drink we may give water with a little wine or when diarrhea is present thin rice, barley or oatmeal gruel. Diarrhea is best treated with bismuth subnitrate 1 to 2 gm. (15–30 gr.), bismuthose 2–3 gm. (15–30 gr.), or with tanalbin or tanningen 0.5–2 gm. (8–30 gr.). Intestinal hemorrhage is treated with cold applications externally and internally with cold nourishment and lig. ferri sesquichlori 3–5%,or gelatine solution.

The organs of respiration require particular attention. Atelectasis and diffuse bronchitis may be treated by liquor ammonii anisati and benzoic acid. The pulse and heart sounds must be very closely watched and if the second sound weakens and a blowing heart murmur is observed in connection with a weak apex beat and irregular pulse we must omit all antipyretic remedies and in spite of the fever resort to energetic stimulation, as wine, musk, camphor, liq. ammonii succinati, caffein (Jacobi [42]) and good nourishment. Inhalation of oxygen may be used, particularly if the peripheral circulation is weak and the extremities cool.

Delirium, jactitation and stupor follow either continued high fever, cerebral complications or otitis media. In case of otitis media it is not wise to delay too long before resorting to paracentesis of the tympanic membrane. When the hyperpyrexia from the general intoxication shows itself in cerebral symptoms we must resort to antipyretic remedies and apply ice bags to the head.

It is sometimes necessary to resort to narcosis somewhat to quiet the restlessness of the patients, and for this purpose chloral hydrate is the best remedy, given in doses of 0.5–1.5 (8–24 gr.) by the stomach or rectum; or we may use the more

[40] s. Hierzu Baginsky: Die Antipyrese im Kindesalter, Hirschwald, 1901, Berlin.

[41] Respecting the application of these antipyretics I refer to the two following articles: 2 Hagenbach-Burckhardt: Baginsky, Henocksche Festschrift, p. 125, ff. 2 Demme: Jahresbericht des Jennerschen Kinderhospitals, 1889.

[42] Jacobi: Archiv of Ped., March, 1885, and Therapeutics of Infancy and Childhood, Philadelphia, 1898, 2 Aufl., auch im Deutsch. übersetzt von O. Rennert, Berlin, 1898, Springer.

recent drugs sulfonal or trional in the same dose. Morphine is prescribed rarely and unwillingly to little children and then in doses of only 0.002–0.008 ($\frac{1}{33}$–$\frac{1}{8}$ gr). The bromides have but little effect. Albuminuria requires scarcely more than alkaline waters as Vichy, Wildunger, Fachinger and others. Urotropine has a favorable effect when from the presence of pus in the urine we suspect an inflammation of the pelvis, of the kidney or the bladder and we wish to render the abundant excretion of typhoid bacteria harmless. We may give 1–1.5 gm. (15–24 gr.) per day.

Parotitis should be treated by means of ice or cold water compresses and inunctions of ichthyol ointment; but if pus develops in the gland we must make an early and free incision under strict antiseptic precautions.

Complications, as periostitis, decubitus, etc., must be treated on general surgical principles by applications of iodoform, acetic acid, corrosive sublimate, etc., and if diphtheria complicates typhoid the early use of diphtheria antitoxine must not be neglected.

During the period of convalescence it is particularly important to watch carefully the action of the digestive organs. If during this stage of the sickness the tongue becomes again coated and the patient develops a slight diarrhea, heaviness in the region of the stomach and a return of fever it will be necessary to diminish the quantity of the nourishment till these symptoms are past. We must be exceedingly careful in passing from a liquid to a solid diet and particularly to a meat diet. It is not safe to give meat for at least a week after the temperature is normal. Bouillon, beef tea, fresh meat juice with a little wine, Scholl's Puro, Valentine's or Brandt's meat juice, Rosenthal-Leub's meat solution, peptone preparations and well prepared leguminous soups will render a meat diet for some time quite superfluous even in very debilitated children.

THE FINSEN LIGHT CURE.

BY H. JOHN STEWART, M.D., CHICAGO, ILL.

HAVING read and heard so much about the Finsen Light treatment in the cure of disease, I decided in April of this year to make a personal investigation to see and learn for myself if it was true that such diseases as lupus and rodent ulcer could be cured by light. I visited several institutions where the Finsen Lamp was in operation. In Manchester, England, in the Salford Skin Hospital, they had a Finsen Light department under the supervision of Professor Brooke, who informed me they were unable to treat half the sufferers who applied for treatment, and they had solicited, by public subscription, $125,000 for the erection of a new hospital for skin diseases, where they would be able to enlarge the "light department" so at least two hundred people could be treated daily, as there were people on their waiting list whom they would be unable to treat, with their present facilities, for an indefinite time. Professor Brooke was most enthusiastic over the wonderful results they were obtaining there.

I next visited the London General Hospital of London, England, and found they were just completing an immense light department that had been established by the present Queen of England, then Princess of Wales, in 1900, who presented the first lamp at that time, and as it was found to be far too inadequate, she had just given a second lamp, and Alfred Harmsworth had also given $50,000 for the perpetual endowment of another Finsen Lamp in this department, and they were then building a platform to receive the king and queen, whom they expected to come June 11 to dedicate this new department, and even with these increased facilities, I was informed by Professor Sequirey there were patients on the waiting list who were unable to receive treatments.

I next visited the Light Institute at Copenhagen and found that all the statements that had been made regarding the Finsen Light were not in the least exaggerated. I had the pleasure of meeting and studying under Professor Finsen himself and was extended every courtesy by Professor Finsen and his assistants at this institution. He seemed very much pleased to describe in the minutest detail the apparatus, treatment, etc., and gave me a detailed history of the Finsen Light.

The Finsen Light is a large, specially constructed arc lamp of 20,000 candle power, or twenty times stronger than an ordinary street lamp, and uses from sixty to eighty amperes of current. This lamp burns a specially made carbon which can only be procured at Copenhagen. In the upper holder is a large carbon, while a smaller one is used in the bottom holder; when properly ad justed for arcing a maximum number of violet and ultra-violet rays are produced. The advantage of the Finsen Lamp over others is in the greater number of violet rays produced. The Finsen Lamp produces a much greater number of chemical rays than sunlight, as the atmosphere absorbs a large percentage of these rays. The light is so intense it is impossible to look at it with the naked eye and it is necessary for all the attendants and patients to wear dense smoked glasses while the lamp is in operation; an aluminum hood about two feet wide surrounds the lamp, which hood is fringed on its lower border with a deep crimson-colored paper skirt to further aid in excluding the diffused light from the patients.

The concentrated rays are carried from the arc to the patients through four telescopic tubes, known as converging tubes, suspended at an angle of forty-five degrees, the tubes containing a series of rock crystal lenses so arranged that reservoirs for running water exists between them. By means of the water screen and rock crystal lenses, all rays but the violet are eliminated, and these rays are converged and concentrated, thus vastly increasing the healing and bactericidal effects.

The heat from the original arc is so intense that to prevent cracking of the lenses and discom-

fort to the patients a stream of cold water is kept constantly circulating through the reservoirs or water screens.

To further concentrate and cool the rays a compressor is provided which consists of two rock crystal lenses so arranged that a chamber for running water exists between them. This part of the apparatus is used to compress the affected area and make it bloodless during the treatment, thus facilitating deeper penetration. The Finsen arc light has been used with marked success in curing many skin diseases, thought until this time incurable, especially lupus and rodent ulcer. During a period of six years the Finsen Medical Light Institute at Copenhagen has grown from a very small shed, where they were only able to treat one patient at a time, to a magnificent institution where they are now treating three hundred people daily, and light institutes have been established in London, England; St. Petersburg, Russia; Paris, France; and Chicago, Ill., where they are all carrying on a similar work to the parent institution.

It has been a popular belief that lupus was a very rare disease and common only in the northern countries, and although it was supposed there was no lupus in London, yet the hospitals are now treating 175 daily, and the management was compelled to install two more lamps and build a separate department, so great has been the demand from people seeking relief. Lupus was considered very rare in the United States, but since the establishment of the Finsen Light Institute in Chicago, the author is informed they have been taxed to their utmost capacity, and they, too, have found it necessary to increase their facilities, as there are now patients on the waiting list who are not able to receive treatment. It seems but a question of a short time until light institutes will be established in every large city in America, because it has proven so efficacious in many other skin diseases, besides lupus and rodent ulcer, such as acne, alopecia, areata, localized eczema, chronic ulcers and nevus. The treatments are given while the patients recline on couches. By firm pressure with the compressors on the tissue to be treated, the blood is removed and more heat can be borne and deeper penetration produced; this compression has another important advantage in that the bactericidal effect is greater because it has been shown that the corpuscles absorb a considerable portion of the rays and thus prevent deep penetration.

The affected area is placed about ten inches from the distal end of the converging apparatus, and the treatments, or seances as they are called, take about one hour daily in lupus and rodent ulcer, and in other skin diseases from ten to twenty minutes, depending upon each individual case.

The results attained have been hardly less than marvelous since from carefully compiled statistics covering a series of over eight hundred cases of lupus treated at the Finsen Institute an overwhelming percentage of cures and an insignificant number of failures is shown, and Professor Finsen goes so far as to say that in lupus vulgarus cures can be obtained in 97% of cases, even where the whole face is involved. In these eight hundred patients, with ages ranging from five to seventy-four years, the average duration of disease was eleven years. This treatment has an advantage over the X-ray in that there is no danger of burning and consequent sloughing. With the light treatment we are dealing with a known quantity, while with the X-ray we have an unknown quantity of uncertain action.

The light treatment causes no pain; a red erythematous spot and blister appears where the light is applied, and in five or six days the scab falls off and the ulcer is healed beneath, and the skin is left free from scar or cicatrix, but red, the redness, however, after a variable period fades and leaves the skin white and uncontracted, except where there has been a loss of tissue from the disease before treatment.

In conclusion, the author would state that the possibilities for the light treatment in the curing of diseases are still unknown, and believes in a limited time it will take an exalted position in the field of medicine and surgery.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

Meeting of Oct. 20, 1903; the president, Dr. J. B. Swift, in the chair.

Dr. Malcolm Storer read upon

SOME QUESTIONS RELATIVE TO EXTRAUTERINE PREGNANCY, WITH ESPECIAL REFERENCE TO TUBAL ABORTION.

Dr. F. H. Davenport: Curiously enough I have had very little personal experience with extrauterine pregnancy and any opinions of mine are based rather upon general principles. As to the question of operating when the patient is in a condition of shock I must say that on the grounds Dr. Storer has outlined I would feel it much safer to operate than to wait till the patient reacts.

Dr. J. L. Hildreth: The dangers of waiting have been borne in on me by experience. It seems to me that waiting is not as good surgery as immediate operation.

Dr. F. A. Higgins: While I am by no means in favor of the vaginal operation for this indication, it has so happened that I have recently performed it on three separate occasions, the patients being in such condition that apparently it was merely a question of draining pus cavities. I shall report the cases later at length. As to the question of the after history of such cases I have under my care now a patient whom I delivered two years ago. Next year she had an extrauterine pregnancy and is now four months pregnant normally.

Dr. G. O. Clark: I have seen in my service at the Massachusetts General Hospital eight

cases. In all the blood count gave 15-20,000 whites and this question of the blood count seems a very important one. There is now in the hospital a case that presents an interesting abnormal symptom, *viz.*, a pulse of 76, although the white count is over 20,000. She has had amenorrhea for three months. The first symptom of trouble was a sudden sharp pain in the lower abdomen yesterday without apparent cause.

DR. J. G. BLAKE: My feeling would be to operate in every acute case, while recovery in the chronic cases seems as frequent when they are not operated upon. So seeing for the first time a case some time after rupture I should probably leave her alone.

DR. G. J. ENGLEMANN: I should like to speak of one point, though it is of no great practical importance, as it means operation either way. I think Dr. Storer did not call attention to the possible confusion of a ruptured right tube with appendicitis. In each case the location of pain is about at McBurney's point, the symptoms are practically the same. I published a case in 1891 where it was quite impossible to tell the conditions apart.

DR. F. S. NEWELL: With reference to the question whether it is better with a living child to attempt to remove the placenta or attach the sac to the wound and allow it to separate of itself I recall a case I saw operated upon where the attempt was made to remove the placenta. The hemorrhage was so great that she died some twenty-four hours later. My feeling is that if the placenta is attached to the mesentery or intestine it is better to leave it.

DR. J. B. BLAKE: In deciding whether to operate at once or to wait, the whole question turns of course on whether the bleeding has stopped or not. I remember some three years ago Dr. Cabot raised the question whether there were any constant variation in the blood that would decide this question. At the time we were unable to find anything that was reliable. I remember that at that time certain foreign observers had said that operation with hemoglobine less than 30% practically meant death, yet I remember several cases that were successfully operated upon with a smaller percentage than thirty.

DR. J. B. SWIFT: Bearing on the question of normal pregnancies following extrauterine I have a patient whose first pregnancy was ectopic. She has had four normal ones since then. In the case of an extrauterine pregnancy at full term with a live child the child should be given every consideration. If it is dead the mother's interests are of more importance and it becomes a question of when it is best to interfere. In a case I reported some time ago I waited six weeks after the death of the child, watching the placenta gradually grow smaller. When I finally did operate it was quite easy to remove child and placenta. We do not know after just what lapse of time the removal of the placenta becomes a simple matter. In my case it was so after six weeks.

DR. ALFRED WORCESTER read a paper entitled

OBSTETRICAL NURSING.

DR. F. A. HIGGINS: Dr. Worcester has given us a paper that we might discuss at considerable length. I do not suppose he expects us to agree absolutely with him in all things. I should take issue with his first statement that he considers the nurse as of more importance in a normal case than is the physician. I should also dissent from some of the educational features that Dr. Worcester would supply, not from any feeling that the nurse would be over-educated, but because I think they are impracticable. I agree entirely that all hospitals should give at least some education in obstetrics.

DR. G. H. WASHBURN: A most important matter in training is that the nurse should be taught to look after her patient from the home point of view rather than the hospital point of view. Hospital methods are not adapted to home needs and often the best hospital nurses are complete failures when they try home nursing. Most hospital nurses have to pick up this knowledge of the difference between hospital and home needs as best they can and it certainly would be a great advantage if to their scientific knowledge there could be added some instruction in home nursing. It is only when a nurse can accommodate herself to household conditions that she can do her whole duty.

DR. A. K. STONE: I am very glad to hear Dr. Worcester has come round to acknowledge that there are grades in nursing — that some should have some training and some more — he did not always hold this view. In a discussion like this we must consider the grade of nurses that we aim at turning out. The great trouble with the training schools is that they aim at turning out nurses fitted to go into the families of the very rich. We are now coming, however, to recognize the fact that there are large classes of society who cannot afford to pay for nurses such as the product of our training schools hitherto. The large hospitals have come to the point when they have recognized that they must add to their curriculum many things hitherto excluded. Up to quite recently, however, there has not been by any means the cordial response on the part of obstetricians that would have been desirable.

DR. H. T. SAWIN: One of the things that should be most strongly borne in on nurses is that they must learn to accommodate themselves to the servants they find in houses. This they get no idea of in the hospitals. I would like to ask Dr. Worcester whether he would be willing to take a nurse's word that the first stage of labor was progressing normally.

DR. NEWELL: I do not think it is the nurse's province to say whether a pregnancy is progressing normally.

DR. J. J. PUTNAM: I sympathize with much of what Dr. Worcester has said which I recognize is part of his general view of raising the standard of nurses. It does not seem to me quite clear what chance a nurse has of ever recouping

herself for all the time and money she has spent in getting an education such as the reader would have them have. I do not fear the nurse's assuming too much responsibility and taking the doctor's place under such conditions. If the doctor finds some of his occupation as a nurse gone he will surely find other fields.

Dr. E. Reynolds: I still see some cases of obstetrics in consultation and the mistake that seems to me to stand out most prominently is dilatoriness and neglect of physiological conditions until they become pathological. The modern trend of thought is that labor must be helped in some way. The average man subjects many patients to unnecessary suffering from lack of small aids in the earlier stages.

Dr. J. G. Blake: The point of the paper that impresses me most strongly is the necessity for a school of midwives. In our smaller towns we need a certain number of educated midwives and in our cities too they would be most valuable. The Italians, for instance, depend largely on midwives. I have seen many bad cases of sepsis among them due to the ignorance of the midwives they were forced to employ.

Dr. Englemann: The questions that the reader has brought up are extremely important. We are now to face face with the peculiar condition that in midwifery the mortality is greater in private practice than it is in hospitals. This is partly due to lack of proper nursing. The question is how to obtain that nursing. A very small proportion of people can pay for nurses such as the reader suggests. The foreigners who cannot possibly pay three dollars a day for a nurse have a right to proper care and any move that will replace the midwife whom apparently we are going to lose is a move in the right direction.

Dr. Worcester: In summing up I can only say that I am sorry Dr. Higgins refuses to assent to my proposition that in normal cases the nurse is more important than the doctor.

I cannot claim the honor of conversion that Dr. Stone ascribes to me. I must have failed to make myself plain, as I have changed my views in no way. I see no hope whatever in attempts at educating a low grade of nurses. I agree that the proper education of midwives would be a most excellent thing, but I feel that their day is past. Their place, can, however, be taken by a system of visiting student nurses who will know when to call in help. I believe it is perfectly possible to educate the nurse to the point of recognizing when the time has come to call in help.

I am living in a community where no woman, however poor, has not a nurse when she is confined — women who never in their lives before had a doctor on such occasions. This is accomplished by the student nurse system, she working under a competent superior. I cannot help thinking that much of our difficulty of coming to an agreement comes from our not recognizing the great differences between the classes of patients nurses are called upon to attend. The rich can have the finished product — the poor can have the student nurse, who will eventually be much better trained than the finished nurse of to-day. Is it or is it not an advantage to the people at large to have the whole business of midwifery in the hands of physicians? There are not enough self-sacrificing doctors to do this as it should be done among the poor. The student nurse will. I believe if there is a large body of well-trained student nurses, ready to send for help at the proper time, it will be a great gain to both the community and the nurses themselves, and, furthermore, such student nurses eventually will become thoroughly equipped obstetrical nurses.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Proceedings of the Thirty-First Annual Meeting, Held at Washington, D. C., Oct. 26, 27, 28, 29, and 30, 1903.

(Continued from Vol. CXLIX, No. 27, p. 739.)

HUMAN AND BOVINE TUBERCULOSIS.

Dr. M. P. Ravenel, of Philadelphia, made some remarks on this subject. During the past year, interest in the question of the relation between human and bovine tuberculosis, has been unabated, and several papers of interest have been published bearing on the subject. In America, Drs. Theobald Smith and Gideon Wells had isolated cultures of the tubercle bacillus from human sources having the characteristics and virulence of the bovine organism. A number of new cases had been reported of accidental infection of man by bovine material, the most important of which was that of Troje, which appeared able to withstand the most severe criticism.

A young butcher in good health, and with no hereditary taint, wounded his left forearm slightly while working on a tuberculous cow. The wound healed under treatment, but six weeks later showed signs of inflammation, and a tubercle formed on the internal face of the elbow. There were two small fistulæ on the forearm and enlargement of the ulnar and axillary lymph glands. A month later the middle forearm was covered with granulations which steadily increased in area, and, in spite of treatment, at the end of two months assumed the character of lupus. Histological examination at this time proved the tuberculous character of the disease. Two years after the injury Troje found an abscess which extended into the deep muscular layers. The pus contained tubercle bacilli and the tissues showed typical tuberculous lesions. Some months after the glands of the left axilla and subclavicular space were extirpated and proved to be tuberculous. All possibility of infection from human sources was excluded by Troje.

Much interest attached to the report made by the Commission of the Imperial Sanitary office of Germany. In all their tests pure cultures were isolated and used for inoculation. Cultures

were obtained from 39 sources, 23 of which were adults and 16 children. There were 19 cases of pulmonary tuberculosis, 4 cases of bone tuberculosis, 2 cases of cervical adenitis, 1 case of genito-urinary tuberculosis, 6 cases of miliary tuberculosis and 7 cases of the digestive tract. Of the 39 cultures examined, 19 produced no lesion in cattle, 9 caused a slight enlargement of the glands of the shoulder, without tendency to generalization, 7 a somewhat more marked involvement of this gland, while 4, all obtained from children, caused a generalized infection. Two of these 4 cases were described as miliary tuberculosis, beginning from a bronchial adenopathy and a mesenteric adenopathy respectively, while the remaining 2 cases were cases of intestinal tuberculosis. The cultures from the two last showed a very intense virulence for calves. The Commission pointed out that 2 of these 4 children did not die of tuberculosis, hence it was concluded that in only 2 out of 39 cases were they able to say that infection with the bovine tubercle bacillus had caused fatal tuberculosis in man.

PROFESSOR ORTH placed a different interpretation on these results. He held that the seven animals which showed marked involvement of the lymph glands of the shoulder should be considered as infected with human tuberculosis; that the infection was not more grave proved only that in cattle as in man, tuberculosis might undergo spontaneous cure. Of the 39 cultures studied, 11, or 28%, were virulent enough to infect cattle.

The author felt that the genetic unity of the human and bovine races of tubercle bacilli, as well as their inter-transmissibility, had been definitely demonstrated. It had also been proven that a certain proportion of persons, chiefly young children, met their death through infection with the bovine tubercle bacillus, but the knowledge at hand did not enable him at present to define the extent of this danger.

CHARACTERISTICS OF THE STEGOMYIA FASCIATA WHICH AFFECT THE CONVEYANCE OF YELLOW FEVER.

DR. H. R. CARTER of Baltimore, Md., read a paper on this subject.

Among the special characteristics of the Stegomyia which affected its role as a carrier of yellow fever are:

(1) Its distribution.

This is, generally, between Lats. 43 N. and 43 S. on the coasts and low plains of Africa, Asia and the adjacent islands; Australia and the Mediterranean basin of Europe.

It is also general on the eastern coast of America from 38 N. to 35 S. Lat. On the west coast it is found at Panama and Guayaquil and its existence is implied from Guayaquil to Acapulco.

In the United States it is general on the coast and low plains of the Southern States, except Maryland.

(2) That it is conveyed by vessels indefinite distances (from Cape Town to Savannah Quarantine); in much greater numbers and more often by sail than by steam vessels.

(3) That it lives a long time — one hundred and fifty-four days being recorded by Guiteras of an infected insect.

(4) That once having acquired the power of transmitting yellow fever it retains it apparently as long as it lives — fifty-nine days being recorded.

A consideration of the four postulates above will render it advisable to safeguard the tropical countries of the east when communication is opened up between them and American ports infected with yellow fever, preferably by freeing the American ports of yellow fever.

(5) That it propagates preferably in artificial containers, but will propagate in pools where such containers are not available.

(6) That in America it has been reported only in the vicinity of human dwellings and seems here not to be a sylvan, paludal or campestral mosquito.

From (5) and (6) the war against this insect in America should be waged about the houses of men, and especially against water in artificial containers. The introduction of a water supply, piped to every house so as to do away with cisterns and water jars, is the most important measure of sanitary engineering to free a town of this mosquito. Next to this is a system of drainage by covered drains to carry off the rain water and prevent pools. Cesspools are not objectionable on this score.

It unquestionably hibernates in the United States either as adult, larva or egg, but if the infected adult hibernates, either a very large proportion of them die, or else the infecting parasite must generally die in the hibernating mosquito. The first seems more probable.

(7) It is essentially a house mosquito, and is inclined to stay about the premises where it has fed. Hence the greater safety of the wholesale district of an infected city as compared with the residence portion.

(8) It does not feed in the dark or in bright sunlight. Therefore, in bright daylight or at night without artificial light are the safest times to be in an infected place.

(9) The cycle of the yellow fever parasite in the mosquito before it can be conveyed to men is generally, in hot weather, about fourteen days or over. Prior to the accomplishments of this cycle (once called the " extrinsic incubation of yellow fever ") the mosquito cannot convey this disease.

(10) It is probably usually conveyed aerially less than 100 yards. In Havana the infected insect is believed to be never aerially conveyed 250 fathoms — 1,500 feet — from the Havana shore.

The direction of the prevailing wind during the day influences its aerial conveyance.

THE EFFECT OF LEMON JUICE IN THE MIXTURE KNOWN AS LEMONADE UPON TYPHOID POLLUTED WATER.

DR. WILLIAM G. BISSELL, Buffalo, New York, presented a paper on this subject. The investi-

gation, he said, was prompted by a newspaper statement purporting as coming from a board of health in one of the leading American cities, that lemon juice in lemonade would render typhoid polluted water safe for drinking purposes. Three different methods of testing were tried: (1) By infecting water with typhoid and adding lemon juice. (2) Infecting glass rods with typhoid and placing them in lemonade. (3) Infecting silk threads and placing them in the lemonade. Culture tests with the first method were faulty. The conclusions drawn were: (1) That lemonade cannot be depended upon in this rôle. (2) That this method of sterilizing typhoid polluted water should be discouraged.

AN EMERGENCY CULTURE MEDIUM FOR USE IN THE ROUTINE DIAGNOSIS OF DIPHTHERIA.

Dr. William G. Bissell, Buffalo, New York, stated in this connection that not infrequently laboratories will run short of their amount of Loeffler's blood serum. The following mixture can be prepared inside of three hours and answers as a good substitute: two parts whole eggs, thoroughly beaten up and 1 part of the 3% dextrose bouillon. Material after being solidified can be autoclaved at 6 pounds pressure.

REPORT OF COMMITTEE ON BACILLUS TUBERCULOSIS IN MAN AND ANIMALS.

Dr. Mazyck P. Ravenel of Philadelphia said that in summing up the available evidence, the Committee felt that there was strong ground for believing in the genetic unity as well as the intertransmissibility of the human and bovine races of the tubercle bacillus.

They considered that it had been positively proven that a certain proportion of persons, chiefly young children, met their death through infection with the bovine tubercle bacillus, but the knowledge at hand did not enable them at present to define the extent of this danger.

STUDIES OF MEDIA FOR THE QUANTITATIVE ESTIMATION OF BACTERIA IN WATER AND SEWAGE.

Mr. Stephen D. Gage and Mr. George O. Adams of Boston, Mass., offered a joint paper which stated that in a report from this laboratory at the Buffalo meeting, figures were presented showing that by simplifying the usual culture media, higher counts of bacteria may be obtained, and that the counts on a new medium, Nahrstoff agar, were much higher than on the usual media. These studies have been continued, and while not completed, certain points are presented for consideration. In standard gelatin or agar, the beef broth is the most fertile source of variation, the amount of the nutrient matter in beef-infusion made by the usual method varying through wide limits. Of the two best-known commercial peptones, Merck's and Witte's, higher bacterial counts are obtained on media made with the latter. Studies of plain agar made with the various kinds of natural water show that in the majority of cases the bacteria naturally present in the given water will develop in greatest numbers in a medium made with the same water. The salts naturally present in commercial agar have a detrimental effect, greater numbers of bacteria developing on media made with agar from which the natural salts have been washed out. Greater numbers of bacteria will develop on media made without glycerin than on the same media containing glycerin. With pure cultures of different kinds of bacteria on standard gelatin, agar or "Nahrstoff" agar the highest counts were obtained, with the species studied, on gelatin and the lowest on "Nahrstoff" agar. A reduction of the amount of "Nahrstoff" in "Nahrstoff" agar from 1% to .5% results in a considerable increase in the bacterial counts with various waters. When cooked in acid or alkaline solution the albumoses of "Nahrstoff" undergo certain changes in composition which render them better food material for bacteria than is the commercial product.

Studies of the efficiency of water filters in removing bacteria when estimated by counts on different media show that there is a considerable variation between the various media, the ratio between the numbers of bacteria in the raw water and in the effluent being affected by the period of incubation, the reaction and the composition of the media. With standard gelatin and Lawrence agar the ratio was less variable between different lots of gelatin.

The writers recommend that a standard nomenclature be adopted for the various culture media, the names used to express, as far as possible, the composition of the media.

(To be continued.)

Recent Literature.

A Text-Book of Operative Surgery, Covering the Surgical Anatomy and Operative Technique involved in the Operations of General Surgery. Written for students and practitioners. By Warren Stone Bickham, M.D., Assistant Instructor in Operative Surgery, College of Physicians and Surgeons, New York; Late Visiting Surgeon to Charity Hospital, New Orleans, etc. Philadelphia. New York, London: W. B. Saunders & Co. 1903.

This book is planned to present to the student and practitioner the surgical anatomy and technique involved in the operations of general surgery; to present in these operations the best technique of modern surgeons with a brief summary of the descriptive and surgical anatomy of the structures involved.

The volume is divided almost equally in two Parts:

Part I. The operations of General Surgery. This includes the operations on the arterial, venous, lymphatic, nervous, osseous, and muscular systems, joints, tendons, ligaments, fasciæ, bursæ, amputations and excisions.

Part II. Describes the operations of Special Surgery classified by regions anatomically, *viz.*, operations on the head, spleen and spinal cord, neck, thorax, abdomino-pelvic, male and female genital organs, hernia.

The author considers that operative surgery is largely applied anatomy; that operative technic is more or less perfect as the knowledge of surgical anatomy and its application during actual operative work is more or less perfect. For this reason surgical anatomy is a conspicuous feature.

In the arrangement of the work in presenting each group of tissues or operations (Part I), or each organ (Part II), the following system is adopted: (1) Surgical anatomy of the region or organ. (2) Surface form and landmarks. (3) General surgical considerations. (4) Instruments required. The above being introductory to specific operations, which latter are considered under the following headings: (1) Title of operation. (2) Description of operation (including its general indications). (3) Preparation of patient. (4) Position of assistant. (5) Landmarks of operation. (6) Incision for operation. (7) Steps of operation. (8) Comments.

In the description of technic the "Incision" receives a separate heading to emphasize its importance. Under "Operation" the various steps are given in paragraphs marked by numbers in heavy type, each paragraph indicating in a general way some change in technique or stage of the operation. The name of the originator of an operation when known is given with its title.

The clinical aspect of the subject is only briefly considered and as a rule with the general consideration of a group of operations rather than specifically in connection with each individual one.

The book is a handsome octavo volume of 984 pages illustrated by 559 excellent cuts which are practically original, and reproductions of specially hand-made drawings. They are well chosen, show unusual clearness, many also great artistic skill. It is satisfactorily illustrated.

Again the author has confined himself strictly to his title, viz., operative technique of general surgery and the operations of specialties, as well as the general considerations usually presented under the title of "Principles of Operative Surgery, Anesthesia, etc.," have been ignored. It is strictly a manual of operative work.

The specific arrangement of the subject is apparently original with the author. It is an excellent one and is systematically observed throughout the volume. The surgical anatomy is fully but concisely given with the operative details. The list of operations selected is a full one and includes practically all those at present in practice, even the most recent. It is fully "up to date" and represents the work of the most noted modern surgeons.

One feature is noted which might perhaps save mental effort on the part of the reader in connection with the illustrations. An illustration is much more readily understood if the explanatory notes are directly connected with it rather than referred to by number or letter. The former method is more graphic and has been adopted with advantage by some of the best books on operative surgery, notably Kocher's.

Taken as a whole the book is distinctly a valuable contribution to surgical literature. It represents a vast amount of careful work and technical knowledge and Dr. Bickham indeed has merited praise and congratulations on the success of his efforts. It is an interesting, instructive manual to the student, and one which he will find quite "solid" reading; while for the surgeon in active practice it forms a valuable résumé of operative work.

A Textbook of the Diseases of Women. By THOMAS A. ASHBY, M.D., Professor of Diseases of Women in the University of Maryland; Consulting Gynecologist to the Mt. Hope Asylum, to St. Agnes Hospital and to the Hebrew Hospital of Baltimore, etc. pp. 661. 233 illustrations. Baltimore: Williams & Wilkins Company. 1903.

As setting forth the personal experience of the author this volume has a certain definite value to the practitioner of medicine; as a textbook it does not reach the high standard of the best of the recently published works on this subject.

A narrative style, an absence of logical arrangement of subjects and crude illustrations give the book the appearance of an amplified syllabus of lectures to students rather than a carefully arranged, comprehensive treatise.

Figure 207, page 576, marked "The Miculitz Drain" (an unusual spelling of Mikulicz, by the way) does not show the gauze handkerchief, and the cord extending through the center of the gauze packing is apparently attached to nothing at the bottom of the pelvis.

In the description of Emmet's operation for laceration of the perineum, page 243, the author inserts a figure taken from Emmet's "Principles and Practice of Gynecology," published in 1884, illustrating Emmet's first operation, now long since discarded by its originator. It is not surprising that the original figures on the succeeding pages give an erroneous impression of the modern Emmet operation. Presumably the printer is to blame for the legend under figures 108 and 109, page 244, which reads, "Emmet's Operation for Complete Laceration," as the figures depict incomplete laceration.

Few modern authors think it necessary to insert in a textbook a diagrammatic representation of the "perineal body," page 31, and we seldom find nowadays a chapter on "Pelvic Hematocele."

The William & Wilkins Company have produced a well-bound book, printed in clear, large type, on heavy paper.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JANUARY 7, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS

THE TRANSMISSION OF PLAGUE.

A FURTHER valuable statement on the question of the transmission of plague comes from the Board of Health of Sydney, Australia, being the official report for 1902. In a previous contribution to the subject Dr. J. Ashburton Thompson, chief government medical officer at Sydney, maintained that the epidemic of plague in 1900 was caused neither by direct communication with the sick nor by dispersion of infected articles nor by place infection. The report before us confirms and amplifies the results then obtained.

Regarding the relation of the rat to the spread of epidemic plague evidence heretofore gathered goes to show merely that both the rat and man are susceptible to an identical infection. It is merely a matter of conjecture that plague is primarily a disease of the rat, that it is ordinarily communicated from rat to man, and that man and the rat under ordinary conditions are reciprocally infective. In other words, the coincidence of the appearance of the disease in man and in rats has been observed, but the causal relationship has not hitherto been established. In the report of 1900 it was held as a justifiable hypothesis that plague-rats constituted the sole source of infection. Further investigation seems, however, to have shown that given plague-rats and man with the disease, it is necessary to find an intermediary host capable of conveying the infective agent from rat to man. It is a far-fetched supposition that the infection might be directly conveyed from the rat to man.

In the report of 1900 it was noted that Simond had suggested two years before that the intermediary might be furnished by the flea or bed-bug. The evidence, however, at that time, was not sufficient to establish this claim, which later investigation has shown to be worthy of serious consideration. The steps by which this conclusion was reached form an interesting study in the investigation of epidemic disease. It was found, when special attention was attracted to the matter, that, although the presence of plague-rats appeared necessary to human infection, contact with these rats was certainly not necessary. It was forthermore shown that plague-infected rats in a building did not lead in many instances to infection of the inhabitants. It was likewise observed that when plague-rats and plague in man occurred simultaneously it was usual for but one person of the household to be attacked. On the other hand, it was noticeable that persons coming together in the same place of employment, though living in widely separated localities, were likely to be infected in common.

Admitting the necessity of a penetration of the human epithelium in order that infection might take place, it followed from these observations that an intermediary host would explain the incidence of the disease under the conditions named. The flea best answered these requirements. Granting this, it appeared that many of the difficulties of interpretation of the spread of the disease were removed. It was found also that the species of fleas which infested rats did not infest man, but that they had no repugnance to him. They will feed on human blood if hungry. This also explains the fact that several, although not all, persons under the same conditions may be infected. The flea, having left the plague-rat, may on the one hand never reach a man, and on the other may reach him at a time when its hunger is not sufficient to induce it to bite an unaccustomed host.

From the foregoing observations Dr. Thompson is led to conclude that Simond's hypothesis of the flea as intermediary host best explains the phenomena of plague as seen at Sydney. In reaching this conclusion he maintains rightly, we think, that he is offering certain facts of observation which strongly tend to uphold his opinion. Much naturally remains to be done before the hypothesis may be unreservedly accepted. For example, it is desirable to show that the flea may be able to communicate the virus many hours, or even days, after it has received it, a matter which may be determined only by direct laboratory experimentation.

The advice given in 1900 as to the manage-

ment of epidemic plague is repeated with renewed significance in this report. It runs as follows:

"The promise of safety for the future lies neither with attempts to prevent the importation of plague-rats (which must fail from time to time), nor with attempts to exterminate the rats infesting the locality to be defended (which we have learned is practically impossible), though both of these measures have their valuable uses, but in habitually excluding rats from inhabited premises. This, manifestly, is a defence which can be set up successfully by local authorities; it requires persistent effort, but involves hardly any expenditure of municipal funds."

This most suggestive investigation is of a part with several which have appeared within the last few years regarding the transmission of epidemic disease. It bears a striking analogy to the studies recently made on so-called spotted fever, in which the gopher and the tick were shown to take part in the transmission of the infection. Such an explanation as this offered by Dr. Thompson concerning the spread of plague seems eminently reasonable from our present point of view, and will no doubt in a very short time be adequately substantiated or definitely disproved.

REPORT OF MASSACHUSETTS HOSPITAL FOR EPILEPTICS.

THE report of the Massachusetts Hospital for Epileptics, dated 1904, is before us. During the comparatively short time of its existence this institution has been doing an increasingly active work in the care of epileptics in this state, and there is now reported a steady advance in the amount of property held and in capability of caring for the inmates. The work of the hospital has increased to such a degree that a third assistant physician has been appointed.

In addition to completing and furnishing several buildings, it has been possible to purchase a farm of three hundred acres located on a hillside directly opposite the present buildings. It is proposed to erect on this land two suitable buildings for the accommodation of sixty patients who are to be separated from the others to do the special work of the farm. This plan will also avert the overcrowding of the present buildings, which is always imminent.

The number of patients in the hospital for the year ending Oct. 1, 1903, was 45 in excess of the preceding year, an increase of about 12%. This has led to a certain overcrowding, and the trustees in their report protest firmly against the unfortunate increase in the number of patients without a corresponding increase in accommodation. They maintain, rightly we think, either that proper accommodations be provided or else that patients should not be admitted, a policy which has not always been carried out in the institutions in this state.

Attention is also called to the fact that no adequate provision is at present made for epileptic children now in the state. Although no definite decision has as yet been reached, it seems probable that the trustees will decide that it is advisable to provide for these children at this institution. No further appropriation is asked this year beyond the ordinary one required for the current expenses of the institution, on the ground that the trustees consider it desirable to complete and perfect work already undertaken rather than burden themselves with an immediate enlargement of its scope. The admirable work which this institution is doing in caring for one of the most unfortunate classes in the community should be generally known. In addition to merely caring for the bodily needs of the patients, systematic investigation of a high chracter is being prosecuted, which will undoubtedly in time lead to conclusions of positive value regarding the care and treatment of the disease. We note in the report that a laboratory is recommended. This certainly should be provided in the interests of present and future patients and of scientific medicine at large.

DISTRIBUTION OF INSANITY.

DR. WILLIAM A. WHITE, Superintendent of the Government Hospital for the Insane at Washington, has recently made a statistical study of the distribution of mental disorders in this country. In making his investigation he has apparently not been led by the usual methods, has had no preconceived ideas, and has allowed the facts which he has observed to speak for themselves. Particularly in the study of the causes of mental alienation he very correctly thinks that the subject is far too complex to be elucidated by mere statistical inquiry. Temperature, altitude and physical factors generally are not sufficient to give an explanation.

It appears from his study, published in the *National Geographic Magazine*, that New England has more insanity in proportion to population than any other part of the country, and that the

proportion grows steadily less as one goes either South or West, with the one exception that the Pacific Coast states show a proportion almost as high as that of New England. Leaving out of account this exception, Dr. White finds that the cause of the fact is to be sought in density of population and in the general struggle for means of subsistence, together with the predominance of mental work in more thickly populated regions.

The people of the West are as a rule hardy and commonly free from the exciting causes of mental disorders, whereas in the South the negroes are proverbially relatively exempt from such affections. To explain the apparent exception to the general rule, as seen in California, Dr. White finds that the Pacific Coast has not yet fully recovered from the gold fever of '49, that it also suffers from the effects of immigration, and that the seductions of intemperance and vice have been particularly conspicuous in that part of the country.

This investigation, so far as it is a statement of observed facts, is of very great interest, but we are inclined to agree with Dr. White in his opinion that the subtle underlying causes of mental disorder are so far below the surface that definite conclusions must be reached with caution.

TUBERCULOSIS IN NEW YORK POLICE DEPARTMENT.

At a meeting of the Board of Health held Dec. 30 a resolution was adopted to the effect that all members of the police and fire departments who were found to be the subjects of pulmonary tuberculosis should be suspended from active duty. This action was taken in consequence of a report from Dr. E. T. E. Marsh, chief surgeon of the Police Department, that seventeen members of this department were suffering from the disease in a stage dangerous to their associates. It was explained by President Lederle that while such suspension might seem a hardship for those affected with tuberculosis, it was really in their interest, as well as that of their comrades. To these unfortunates it afforded the one chance of recovery, while others were protected from possible infection. The closeness of the association in which policemen and firemen are obliged by the nature of their duties to pass a considerable part of their time renders tuberculosis especially dangerous to their companions, unless they take precautions more minute and more nearly constant than can reasonably be expected from them.

MEDICAL NOTES.

Herter Lectures of the Johns Hopkins Medical School. — Under the foundation for a lectureship, made by Dr. and Mrs. Charles A. Herter of New York in 1903, it is announced that Professor Paul Ehrlich has been chosen to deliver the first series of lectures. The object of the lectureship is to promote a more intimate knowledge of the medical research of foreign investigators.

New Eye and Ear Infirmary. — Plans have been completed for a new Eye and Ear Infirmary in Newark, N. J., which will be erected on Central Avenue, near Washington Street, at a cost of $60,000.

Oysters a Cause of a Typhoid Epidemic. — As a result of their investigations regarding the cause of a recent outbreak of typhoid fever in that city, the health authorities of Orange, N. J., have arrived at the conclusion that it was due, not, as at first supposed, to a contamination of the water supply, but to the consumption by the persons affected of oysters procured from infected beds.

Centenarians. — The death of Mrs. Mary Holmes Fuller, at Palatine Bridge, Va., at the reputed age of one hundred and one years, is announced. Robert C. Harper, said to be one hundred and four years old, also died last week in Minneapolis.

New York and New England Association of Railway Surgeons. — At the thirteenth annual meeting of the New York State Association of Railway Surgeons, held at the Academy of Medicine, New York City, Nov. 12-13, 1903, a vote was taken and unanimously carried to change the name of the association to New York and New England Association of Railway Surgeons. This change is expected to greatly extend the work of the association.

French Congress of Climatotherapy. — The first French Congress of Climatotherapy and Hygiene of Towns will be held at Nice from April 4 to April 9, 1904. Professor Chantemesse has been named president, with Professor Renaut (Lyon), Professor Grasset (Montpellier), Professor Calmette (Lille) and Dr. Balestre (Nice) as vice-presidents. The announced discussions will take up five questions: The Climate of the French Mediterranean Coast; Adaptation of the Individual to Climate; Influence of the French Mediterranean Coast Climate on Tuberculosis and Tubercular Patients; The Influence

of Climate on the French Mediterranean Coast on Rheumatism and on those subject to Rheumatism; Disinfection of Towns. Special facilities and rates will be granted to members of the congress and their families.

CHICAGO'S HEALTH. — Chicago's Health Commissioner reports for the week ending Jan. 2: Including the 587 theater-fire deaths, accounted for by the Coroner's office and the Police Department, but not yet reported at the close of the year to the Bureau of Vital Statistics of the Department, the total deaths for 1903 will number 28,940 instead of the 28,353 given in the appended statement of mortality for the year. This will increase the death rate from 15.04 to 15.35 per thousand of population. Deaths from violence were already more than 12% in excess of the average for the period since the census year 1900; but these 587 theater deaths swell the excess to 41.5% over the yearly average of violent deaths.

Even with this addition to the total mortality the death rate is 6% lower than the yearly average since 1892, although it is 8.2% higher than that of 1901 and 5.3% higher than 1902.

ANY comment on the features of the month or of the week would read like the veriest platitudes in the presence of the year-end horror — the inevitable aftermath of which has already begun in sudden death among those with crippled hearts and in dethroned reason among those of unstable nervous organization. All such should shun further excitement, keep away from crowds, and strive to forget.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Jan. 6, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 82, scarlatina 39, typhoid fever 8, measles 215, smallpox 0.

PUBLIC BEQUESTS. — According to the will of the late Mrs. Mary D. Converse of Malden, the Malden Home for Aged People receives $2,000; Roxbury Home for Aged Couples, $2,000; the Woman's Charity Club Hospital, Roxbury, $2,000; and the Malden Hospital, $2,500.

GLANDERS AMONG CAMBRIDGE HORSES. — In the annual report of Dr. C. E. Hadcock, inspector of animals for Cambridge, it is stated that there has been an alarming increase in the number of cases of glanders among horses in that city. During the year 60 horses have been quarantined, and 54 were shot. Action has already been taken toward disinfection and fumigation of possibly infected places.

FIRE IN TAUNTON INSANE HOSPITAL. — On the night of Jan. 4 fire broke out in the linen room of the west wing of the Taunton, Mass., Hospital for the Insane. Notwithstanding a considerable overcrowding of the wards, the patients were rescued. The loss is estimated at about $50,000, in which is included the autopsy room, the pathological laboratory and library.

BOSTON DEATH RATE FOR 1903. — The unprecedented low death rate of 17.70 per thousand of the population of Boston is reported for the year 1903. The death rate in New York for the last year was 18.19, a record which falls behind that of Boston by .49 per thousand.

BRIGHAM WILL UPHELD. — Judge Colt of the United States Circuit Court handed down a decision Dec. 30, by which the Peter Bent Brigham Hospital receives about $5,000,000. This decision is the outcome of an effort on the part of the heirs-at-law to overthrow the will on certain legal technicalities. Unless this decision of Judge Colt be taken to the United States Supreme Court, no legal difficulties will stand in the way of the building of the hospital. The trustees of the fund had already purchased part of the property acquired for the new Harvard Medical School buildings.

DEDICATION OF PEABODY HOME FOR CRIPPLED CHILDREN. — The New England Peabody Home for Crippled Children at Hyde Park was dedicated Dec. 29, with appropriate exercises. An added tract of land was given by Mr. Bleakie, giving the home a street frontage of 372 feet. Dr. R. W. Lovett in his remarks drew attention to the economic value of the surgical treatment of crippled children as being an ultimate relief to the state.

RHODE ISLAND HOSPITAL. — The annual report of the Rhode Island Hospital for 1903 makes the following statement: With an endowment of but $150,000, a portion of which was pledged to raise money for the completion of these buildings, this Hospital opened its doors in October, 1868. In the succeeding year it treated 112 patients; whereas during the year ending Sept. 30, 1903, 4,150 patients were treated, and this is an increase over the preceding year of 663, or 19%. The average daily number of patients was 232, against 211 in the year preceding, an increase of 10%.

Public Institutions Conference. — At the quarterly meeting of the Public Institutions Conference, held at the Mayor's office last week, it was reported that the number of persons admitted to various state and municipal institutions through the registration department was 980, being an increase of 79 over 1902. Twenty more than the preceding year were sent to Tewksbury, and four more to Long Island. It is recommended by the trustees of the Long Island institution that an x-ray apparatus be installed as soon as possible with special reference to the study of rheumatic affections. Both of the city insane hospitals are overcrowded, with a total of 569 patients.

NEW YORK.

President of Board of Health. — Dr. Thomas Darlington, who has been appointed by the new mayor President of the Board of Health, and who is the first medical man to occupy that position during the existence of the department in its present shape, is the most prominent physician in the Kingsbridge district of the Borough of the Bronx. He is a graduate of Princeton, and received the degree of M.D. from the College of Physicians and Surgeons, New York, in 1880. He was a charter fellow of the Medical Association of the Greater City of New York, and belongs to most of the prominent medical societies of the city. Among the positions held by him are those of attending physician to the New York Foundling Hospital, consulting physician for diseases of children to the French Hospital, and attending physician to St. John's Riverside Hospital, Yonkers. In view of the large infant mortality which usually attends the summer season in New York, and of the constant increase of contagious diseases among the children of the tenements. it will no doubt be of considerable advantage to have at the head of the Health Department a man who is especially identified with the subject of pediatrics.

Increase in Insane. — The statistics of the New York State Commission in Lunacy show that there has been an increase in the number of insane in the state during the past year amounting to about 40% above the normal. Their observations indicate that there is a relation between the increase of insanity and the development of industries which is sufficiently pronounced to render doubtful the popular belief that the isolation and monotony of farm life are conducive to insanity, especially among women.

Bequests by Joseph Stickney. — Among other charitable bequests in the will of the late Joseph Stickney of New York are $5,000 each to the Wilkesbarre (Pa.) City Hospital and the Margaret Pillsbury General Hospital, Concord, N. H.

Entering Class, Columbia Medical School. — In the annual catalogue of Columbia University, just issued, it is shown that in the School of Medicine the entering class is the smallest for many years, but the average quality of the class is described as the best in the history of the college, 60% of the students holding degrees, and over 90% having had at least one year of college training before beginning their medical work.

Pneumonia. — Pneumonia has been added to the list of diseases in New York which must be reported to the Bureau of Contagious Diseases as communicable. This action has been precipitated by the somewhat marked increase in deaths from this disease.

Speculative Evidence. — Some two years ago Florence Briggs of Buffalo, while traveling on what is known as the Belt Line of the New York Central and Hudson River Railroad Company in that city, received an injury to the spine in consequence of a collision. On the trial of an action for damages which she brought against the company, expert physicians testified that her injuries were such that several of her internal organs might be affected, and, in the end, permanently. The Court of Appeals has now decided that such evidence was speculative, and should have been excluded. " It is undoubtedly true," it is stated in the opinion, which is by Judge O'Brien, " that in an action to recover damages for personal injuries the evidence of experts as to future consequences which are expected to follow the injury are competent; to authorize such evidence, however, the apprehended consequences must be such as, in the ordinary course of nature, are reasonably certain to ensue. Consequences which are contingent, speculative, or merely possible are not proper to be considered in estimating the damages, and may not be proved. We think this rule of evidence was violated in this case, since the learned trial judge permitted to stand, for the consideration of the jury, evidence which was speculative and conjectural. Indeed, the medical experts in the case, upon the examination of the plaintiff's counsel, were permitted to state numerous things which might result as a consequence of this injury."

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, DEC. 26, 1903.

CITIES.	Population Estimated, 1903.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported, 3,439; under five years of age, 881; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 753, acute lung diseases 732, consumption 376, scarlet fever 45, whooping cough 15, cerebrospinal meningitis 7, smallpox 20, erysipelas 11, puerperal fever 6, measles 29, typhoid fever 52, diarrheal diseases 81, diphtheria and croup 111.

From whooping cough, New York 3, Chicago, 1, Philadelphia 5, Baltimore 1, Providence 1, Boston 3, Fall River 1. From smallpox, Philadelphia 14, Pittsburg 6. From cerebrospinal meningitis, New York 6, Chelsea 1. From erysipelas, New York 4, Chicago 1, Philadelphia 4, Pittsburg 1, Cambridge 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Dec. 12, the death-rate was 19.2. Deaths reported 5,553; acute diseases of the respiratory organs (London) 234, whooping cough 97, diphtheria 67, measles 121, smallpox 3, scarlet fever 30.

The death-rate ranged from 6.3 in Grimsby to 32.0 in Merthyr Tydfil, London 18.9, West Ham 16.1, Brighton 22.0, Southampton 14.2, Plymouth 26.5, Bristol 18.6, Birmingham 21.4, Leicester 15.4, Nottingham 18.9, Liverpool 24.0, Bolton 22.0, Manchester 17.9, Salford 18.6, Bradford 19.7, Leeds 19.8, Hull 15.7, Cardiff 18.1, Rhondda 18.7, Kings Norton 13.1, Sunderland 18.5.

METEOROLOGICAL RECORD.

For the week ending Dec. 26, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING JAN. 2, 1904.

R. O. MARCOUR, assistant surgeon. Detached from the "Franklin" and ordered to the "Dixie" for duty with the Panama Marine brigade.

J. M. BRISTER, assistant surgeon. Detached from the "Isla da Cuba" and ordered home.

J. A. GUTHRIE, passed assistant surgeon. Ordered to the "Franklin."

G. F. FREEMAN, passed assistant surgeon. Ordered to the naval station Olongapo, P. I.

RECENT DEATHS.

AUGUSTUS D. RUGGLES, M.D., of New York, died on Dec. 27, from carcinoma affecting the liver and other organs. He was sixty-three years of age and was graduated from the medical department of the University of Pennsylvania in 1862. During the Civil War he served with distinction in the medical corps of the Army of the Potomac. He practised for many years in New York, and among the positions of honor which he had held was that of vice-president of the New York County Medical Association. He was one of the organizers and incorporators of the Medical Association of the Greater City of New York and was its treasurer from the founding of the society in 1899 up to the time of his death.

ANTON EIDENBERG, M.D., of New York, died in St. Luke's Hospital in that city, of pneumonia, on Dec. 31. He was eighty-six years old, and was a native of Hessedarmstadt, Germany. He was graduated at Giessen in 1846, and also received the degree of M.D. from the New York University in 1881. During the Civil War he was surgeon of the Eleventh New York Regiment. He had practised in New York for over fifty years, and was long an attending surgeon to St. Luke's Hospital.

JOHN MARTIN OTTO, M.D., of New York, a graduate of the University Medical School in 1888, died in the New York Hospital on Dec. 29, from a fracture of the skull received in a fall.

CARDIAC DISPLACEMENT.[1]

BY ARTHUR K. STONE, M.D., BOSTON,

Physician to Out-Patients at the Massachusetts General Hospital.

CARDIAC displacement, while not a subject of distinctly practical importance, nevertheless is one which has aroused considerable interest during the past decade, especially in France, where there have appeared a number of excellent papers calling attention to the general erroneous ideas which have been held regarding the subject. As most of what has been said by the members of the Lyons school is also applicable to much of the teaching hereabouts, it has seemed worth while to review the subject and to add my observations, which are based on the study of more than nine cases of permanent cardiac displacement, in addition to a number of cases seen in the ordinary course of acute pleurisy and pneumothorax.

Besides Sir R. Douglas Powell very few other observers have reported more than two or three personal observations, and the total number confirmed by autopsy or X-ray examinations is remarkably small. The most recent and complete résumé of the subject is to be found in the Thesis of Alaux, a student of Professor Pic of Lyons, and doubtless reflects accurately the teaching of that school. It is unfortunate that in his desire to give credit to Professors Bard, Pitres and Pic, he has neglected to quote the correctb servations of Sir Douglas Powell, made in 1869 and 1876. Powell's results were obtained from the study of a goodly number of cases, not only clinically but also at the autopsy table. And to these accurate observations are added experimental studies serving to explain the conditions found. Not only has Powell's work not been quoted by the French writers, but it has also been forgotten by recent English clinicians, who have speculated much regarding the position of the displaced hearts they had observed, when a reference to these papers would have answered all their questions. Symes of Dublin in 1892 disputed Powell's statement as made in his book on the "Diseases of the Heart," evidently without looking up the work on which Powell based his assertions.

The subject of displacements of the heart naturally divides itself into two general divisions, the congenital displacements of the heart, and the acquired or pathological displacements. About the former probably there has arisen the greater amount of dispute, while the latter has given rise to the greater amount of erroneous teaching.

The question at issue is, does such a condition as congenital dextrocardia without an accompanying transposition of all the viscera in the body exist unless accompanied by other malformations of the heart? Cases of transposition of all the organs of the body have been reported from time to time since the first observation by Petrus Servius was made in Rome in 1643. (Collection of cases by Gruber.) As a part of this process the heart is involved in the general transposition and points towards the right, the aorta also arching to the right instead of the left, with the valves of the heart changed to meet the new condition of things; that is, the mitral valves are found in the right ventricle, which is thick-walled and of course communicates with the aorta, while the left ventricle is thin-walled and has tricuspid valves, and communicates with the pulmonary artery. In every way the hearts in the transposed cases are reversed from the ordinary conditions, that is, they are mirror hearts.

It has been supposed that in a number of cases where the heart either actually or apparently pointed to the right, without any transposition of the other viscera, there was present a congenital dextrocardia. It has been assumed that there was a mirror heart also present, the conditions holding as in cases of complete transposition of all the organs. The reported cases of dextrocardia are few in number, and the autopsies when dextrocardia has been suspected are very few indeed.

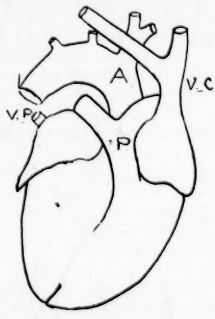

FIG. 1. — Mirror heart.

Of the authentic cases, first of all come a small group where the condition has been noted at the

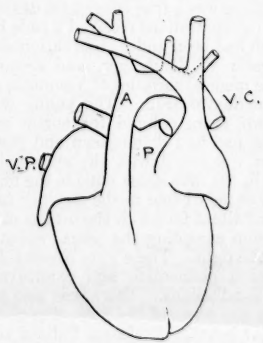

FIG. 2. — Inverted heart. Aorta arches to the left.

[1] Read at a meeting of the Boston Society for Medical Improvement, Nov. 16, 1903.

autopsies of young infants, and here the dextrocardia has practically always been accompanied by malformation of the heart itself, most frequently showing itself in absence of the ventricular septum. There is, however, so far as I can find, no case on record of true mirror heart. Graanboom, however, has a fine case of congenital dextrocardia, which was found in a man of thirty-three, who, dying of nephritis, had never had any manifestations arising from cardiac deformity, although at the autopsy there was found a much narrowed aorta. Here, the axis of the heart was from left to right; the apex, however, was not far beyond the edge of the sternum, although in life the strongest impulse was at the right mammary line. From the right ventricle, which was thick-walled, arose the aorta, but the valves were tricuspid instead of mitral. This is the nearest approach to a mirror heart that has been reported. There are, however, said to be similar malformations to this on record, without any deviation in the usual axis of the heart.

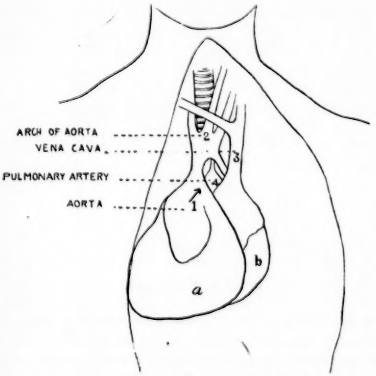

FIG. 3. — Graanboom's case. Like Fig. 2.

Occasional cases have been reported where from clinical observation it has seemed during life that there was a true congenital dextrocardia, but such interpretations received a rude blow in a case which had been under observation since 1888 by Professor v. Bamberger, and demonstrated before the medical societies of Vienna as a case of congenital dextrocardia. The young woman of twenty-two years entered for aortic regurgitation. She had had rheumatism and pneumonia. The heart was found with the apex pointing to the right in the fifth space outside the nipple. In 1896 this patient came to the autopsy table, and Professor Paltauf found all the organs in the normal position excepting the heart, which pointed towards the right. There were present, however, an adhesive pericarditis and extensive pleuropericardial adhesions. There was also a depression upon the dome of the liver, due to the position of the heart. Professor Paltauf refuses to recognize the case as one of congenital origin, but considers that it was consequent to the unrecognized inflammatory processes, which had given rise to the conditions found. He further states that he has met with pericarditis in a seven-months' fetus, and therefore concludes that changes in the heart's axis may possibly be started by such processes, and not be due to real change in the development of the organ.

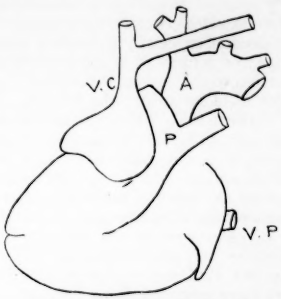

FIG. 4. — Heart drawn to the right.

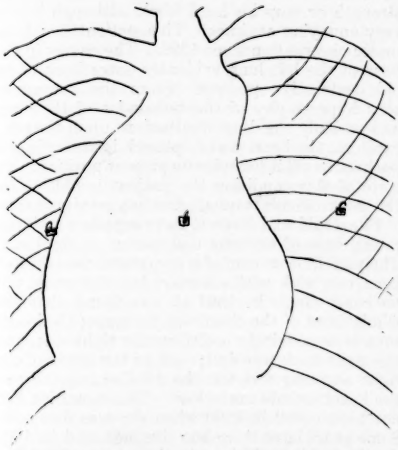

That it is often difficult to get any history of really extensive inflammatory processes I had illustrated in one of my own cases.

Here the heart was in about median position with the apex behind the sternum. The patient declared that he had never been sick, and no questioning could make him acknowledge the fact, and yet when examined with the fluoroscope the whole lower part of the left side of the chest was found to be in shadow, showing that at some time there had been an inflammatory process which was quite sufficient to account for the position of the heart. Other of my patients have only given a history after prolonged and careful cross-examination. From the literature and my own experience I should quite agree with Garel (1902), who refused to diagnose a case as congenital dextrocardia where the apex was undoubtedly to the right, but where a right-sided pleuritic effusion had also been present, as was demonstrated by the shadow showing in the fluoroscopic examination.

One of my cases, however, may possibly come among the rare congenital cases of dextrocardia. The patient is a young man aged twenty-three, who was seen first in 1901. He gives no history of thoracic disease. Since the age of thirteen he has had attacks of epilepsy, much more severe during the past seven years. The hospital record states that the apex is in the fourth right interspace, 8 cm. from the median line. The other organs are in a normal position.

I. A recent careful re-examination shows the greatest cardiac impulse as above stated. With the fluoroscope the heart is much more median than would be expected, and no sign of an apex is to be seen. The portion of the heart at the place of the maximum pulsation is evidently the base. The general position of the shadow shows distinctly that the apex lies behind the sternum.

The space occupied by the cardiac shadow is large. The whole of the right side is slightly hazy when compared with the left side. All that can be asserted is that there is no history to be obtained of inflammatory disease, nor is there any distinct evidence of such having taken place. It is about the picture that a case like that reported by Graanboom would be expected to present. On the other hand, the position, in general that of a heart displaced by mechanical means, and the slight general shadow of the right side of the chest, make all positive assertions in regard to the case impossible at present. All cases where the diagnosis has been

Displaced heart. Congenital (?). Accurately traced from an x-ray photograph. *a*, *b*, *c* show position of the nipples and center of the sternum.

made on the clinical examination alone must be excluded in the light of autopsies and the conditions revealed by the use of the fluoroscope.

My own conclusions are only slightly different from those of the Lyons school, namely, that almost all the known cases of dextrocardia have been accompanied with evidences of extensive malformation of the heart; that no real case of mirror heart, true dextrocardia, is on record. That all cases where the heart does point towards the right, if there are traces of pleurisy or pericarditis having been present, must be considered as acquired conditions unless proved otherwise by autopsy. Nevertheless, the case of Graanboom's shows that a congenital dextrocardia, though not of the mirror heart variety, can exist and give no symptom of defective heart-structure.

II. Displacements or dislocations of the heart due to pathological conditions are to be divided into three general groups: the first due to simple disturbance of the normal atmospheric equilibrium existing in the chest; and the second due to the distorting action of adhesions of an inflammatory origin. The former represent the unrestrained movement of the heart in the presence of pleural exudate, pneumothorax, or of a large cavity within the lung, or any other condition causing sclerosis or shrinking of one lung; the latter, the dislocations due to adhesions forming in the course of inflammatory processes which involve the pleura and pericardium.

The third group is associated with the presence of an aneurism or a new growth within the chest so developing as to displace the heart. With this last group this paper will not deal.

A case where adhesions played an active part in causing dislocation of the heart first called my attention to the subject of cardiac displacements. The patient, a woman of forty-seven, came to the House of the Good Samaritan with the history of having had a double pneumonia which had attacked the bases of both lungs. At entrance the pneumonia in the left lung was said to have been unresolved, although several weeks had elapsed since the attack. I found on examination dulness at the right base, with modified vesicular respiration and a few fine râles. At the left base there was flatness and absence of respiration. After observation for a few days I was tempted to see if I could not discover pus with an aspirating needle, but very careful examination disclosed in several places small areas of distant vesicular breathing, and I concluded that there was no distinct pocket of pus present. At this time the apex beat was noted as being situated 8 cm. to the left of the sternum. The patient gradually gained in strength and was up and about the ward, but very little improvement could be detected in the respiratory signs at the base of the left lung. After a temporary absence from the hospital I found on my return that the patient's condition still remained about the same. To try and get a better respiratory condition hydrotherapeutic measures were adopted. The patient was placed in a bath-tub and cold water was dashed over her by the nurse. It was hoped in this way to cause forced inspiration and to bring into action portions of the diseased lung, This was repeated three times during the week. Preparation for the transfer of the patient to a convalescent home having been arranged, a final examination was made. At the first glance at the chest the heart's impulse was seen to be in the axillary region. There was resonance where before there had been the normal area of cardiac dulness, and the apex impulse was 16 cm. from the median line. A fluoroscopic examination showed clear light transmission occupying the normal area of cardiac shadow, while all trace of the heart itself was lost in the general shadow obscuring the base and outer portion of the left chest.

It seems to me that what had occurred is as follows: Owing to the great gasp which the patient gave at the first application of the water, a portion of the lung which had been previously contracted expanded and escaped from its adhesions and pushed into the place of least resistance; ballooning up, as it were, and pressing the heart outwards so that it was pushed into the space it

now occupies. There was no real disturbance from the movement of the heart more than the severe shock which the patient laid to the first application of the cold water, but I am inclined to attribute the feeling of discomfort to the movement of the viscera then taking place. For some time there were no adventitious sounds to be heard over the heart, but later a soft blowing murmur developed, and a year later some irregularity was noted. The sputum was repeatedly examined for bacilli of tuberculosis without finding any present, although some cough and expectoration continued. At my request Dr. Chandler of Medford examined her in March, 1903, and reported no murmur or irregularity, and the cardiac impulse 16 cm. to the left of the median line.

The great interest in this case lies in the sudden movement of the heart and the little corresponding shock or discomfort occassioned by the seemingly violent displacement of the viscera within the chest. Very few indeed of the patients whose cases are to be found reported in the literature of the subject experienced any inconvenience from the malposition of the heart. Of sudden movements, the one most nearly approaching the one reported above was the case of a medical student (Cochez) who had tuberculosis, and was known to have had a cavity in the right lung. One night on retiring he heard and felt the heart beating on the right side, and about a week later, when he was again examined by his physician, the heart was found dislocated to the right. There was no discomfort noticed by this specially intelligent patient to tell exactly when the movement took place, and yet it probably occurred during the day in which it was noted. Moutard-Martin had also a case where the change was noted by the house-physician probably soon after it occurred, but as there was no discomfort no report was made to the visiting physician.

In the case of a young man examined by me in 1902 where I found the heart displaced upwards and to the right side I was told that the last time he was examined the upper right side of the chest gave a very hollow sound, and that he was informed that there was a cavity there. Here again there was no discomfort to tell when the marked cardiac displacement took place.

Another case illustrates how marked dislocation can exist and yet give no symptom either at the time of its occurrence or discomfort later, although the patient may lead a laborious life. The patient's heart was not in its usual position, and in the place occupied by its normal dulness there was resonance and a clear transmission of light when examined with the fluoroscope. The greatest cardiac impulse was to be located in the left mid-axillary line, and the sounds were to be best heard in the back, mingled with friction sounds and sounds indicating a cavity in the lungs.

This patient has no history pointing to the time of the dislocation. Indeed the whole process was discovered in the course of a routine examination of the chest for the purpose of explaining the cause of cough and expectoration which occasionally, for the past few years, had given him much discomfort. The patient was a stone-cutter. No bacilli of tuberculosis have been found in his sputum, though the sputum has been examined from time to time for several years. Very close questioning finally brought out the fact that about 1886 he had been so weak and sick from a cough that he had given up work for a month or two, but that he had speedily recovered and had even forgotten the fact, only recalling it on talking the matter over with his family. The cough for which he had come to the clinic had appeared only in the past few years and had not been of such a nature as to cause him to lose strength or stop his hard work, although it was very annoying at times. This patient has been under observation since 1899. The cavity in the base of the left lung evidently dates back to an old destructive process. From the compensatory hypertrophy of the remainder of the lung, and possibly the drag of adhesions upon the pericardium, the heart was displaced downwards and backwards till it occupies its present position. In spite of this condition the patient is able to do the most difficult manual labor in a granite quarry.

Fitzgerald and Everett have reported an interesting case of extreme dislocation of the heart. The patient, a woman of sixty, stated that she had been very sick with pleurisy, but this could not be confirmed. In 1894 it was found that the whole front of the chest was resonant; the heart-sounds were faintly heard on the right side, and the right back was dull; and at the angle of the right scapular was felt the cardiac impulse and the heart sounds were clear. This condition had not been noted in 1890 when she was first seen. Some years later there was dyspnea and in 1900 she died of bronchitis. At the autopsy the lobes of the left lung were found to be practically anterior and posterior rather than upper and lower, as the lower lobe extended from the diaphragm to the apex behind, while the upper lobe extended across the whole front of the chest and was adherent to the costal pleura of the right side of the thorax in the mid-axillary line. The right lung was completely retracted.

The heart's position was nearly vertical, and the right ventricle was so placed that it must have been the portion of the heart giving the cardiac impulse at the angle of the right scapular.

The recent case of Garel (1902), where the heart, following an extensive right-sided pleurisy, had been drawn, so that the apex beat was in the fifth interspace in the right mammary line, is another instance showing the distortion possible from adhesions.

In the many cases of so-called dextrocardia following pleurisy and penumonia the heart is held displaced to the right by adhesions developing in the course of an acute inflammatory disease and either drawing or securing the displaced heart in its unusual position.

None of the above-mentioned patients, and none of my other patients with permanently displaced hearts from whatever cause, have had any

uncomfortable symptoms referable to the heart. Nor in any of the many reported cases has the displaced heart given trouble in virtue of its unusual position. And only a few patients of the reported cases have realized at all that the heart was displaced.

While the movements of the heart influenced by the presence of adhesions and the presence of cavities or sclerosed lung tissue with emphysemata of the remainder of the lung or of the other lung are often erratic, on the other hand the movements of the heart caused by the presence of fluid or air in the pleural cavity, or by the contraction of one lung in whole or in part, are practically subject to certain definite rules or laws when uncomplicated by adhesions.

It has been a matter of surprise to find out how little was definitely known about this condition of frequent occurrence. The number of accurate observations reported is very small, even since the introduction of the x-rays as an aid in the examination of the chest. The post-mortem examinations have been few in number, and many of these make no note of the really important fact, — *i. e.*, the exact position of the heart, — being simply content to make the statement that the heart was found as in life to the right. Many pathologists have never seen the condition or at least never considered it of sufficient importance to have made mental note of any cases they may have seen. One of the reasons why it may have escaped notice is that the heart if not held by adhesions will often slip back into its proper position when the chest is open and the pressure within the pleural cavities has been made equal. Such cases are on record, where the heart has been demonstrated during life to be to the right of the sternum, and at the autopsy been found in its normal place, and the space which it has occupied on the right side over a cavity in the lung been plainly visible. Powell also found that the heart when pressed towards the right tended to sag back into place unless held in position by long pins thrust through the heart. Some pathologists who are inclined to think that the backward movement of the heart cannot take place so rapidly, explain the fact that they have not noted the condition oftener as due to the relaxation of the diaphragm after death, and the consequent greater capacity of the pleural cavity. Thus the heart is drawn back to its original position again.

The anatomists consulted have been decidedly surprised to learn that movements of the heart were at all common and had not considered the matter, only it had seemed on general principles that the base was the immovable portion of the heart, while the heart's apex appears to be freely movable. Probably the erroneous idea which has been held by so many that the heart in case of a left-sided exudate became reversed, with its apex pointing to the right, has been due to the manner in which the heart has been seized by the pathologist, and drawn upwards and to the right at post-mortem examinations after the opening of the pericardium.

The movements of the heart in the presence of effusion, or air in one side of the chest, depend on the following anatomical and physiological conditions, which may be modified by certain pathological conditions which may be present:

The heart, enclosed in the pericardium, hangs from the great vessels at its base and lies between the two pleural cavities, which are vacuum chambers. In these vacuum spaces are elastic, expansile bags, the lungs, in connection with the outside air. If a small wound in the chest-wall occurs, the lung does not at once collapse, but rather the lung seems to put forth almost intelligent efforts to cover the opening and prevent the ingress of air. Even in cases where the lung has been compressed into a small compass by the presence of an effusion the active expansive power of the lung asserts itself as soon as the exudate is withdrawn, as is shown by the force with which the pus flows from an opening in the thoracic wall in the cases of empyema. This active participation of the lung in tending to expand from its internal resiliency is denied by some observers, who believe that all the expansion is due to coughing, which distends the lung by the closing of the glottis and the consequent increase of the pulmonary pressure. These men would deny that any of the movements of the heart were dependent on anything besides the ordinary laws of physics, and consequently that the active resiliency of the lungs does not have to be taken into consideration. However this may be finally settled, the anatomical position of the heart is of the greatest importance as regards the forces leading to its movements. The heart rests on the dome of the diaphragm, enclosed in the pyramidal pericardial sac whose base is continuous with a part of the fibers of the upper portion of the diaphragm, which thus makes a firm flooring on which the heart is bedded. From this base the sac of the pericardium has its origin, being held in position by three supporting ligaments: (*a*) the suspensory, which is attached to the body of the third dorsal vertebra; (*b*) the cervical, which merges in the aponeurosis of the neck, which in turn is attached to the hyoid bone; (*c*) the sterno-pericardial, attached to the anterior face of the sternum and the first rib.

Any weight, like an exudate, in the cavity, tends to depress the diaphragm and to put these ligaments on the stretch and thus presents a firm resisting wall so that the fluid shall not press directly upon the heart and hinder its action.

If the effusion is on the right, the wall of the pericardium becomes a rigid partition, behind which the auricles have protection. If on the left side, the ventricular portion becomes tense and vertical, and thus presses against the apex, moving it laterally till in the extreme it goes behind the xyphoid. When this point is reached the right portion of the pericardium is put on the stretch and opposes further lateral movement. The extent to which the pericardium allows the apex to move is towards the left about 5 to 6 cm. and towards the right about 12 to 13 cm.

The movements of the heart uncomplicated by

pleural and pericardial adhesions are to be divided into three groups:

(1) Those brought about by the presence of fluid in the pleural cavity.

(2) Those caused by pneumothorax.

(3) Those due to the presence of large cavities in the lungs, disturbing the equilibrium of the inter-thoracic pressure.

Although the laws hold good for effusions on both sides of the chest, yet as the displacements to the right following left-sided pathological conditions are more marked and more interesting, these alone will be considered.

A glance at one or two diagrams will show how triangular shaped is the outline of the heart — how its right border is nearly vertical and the lower border nearly horizontal, while really only a small apical portion projects beyond the mass known as the base of the heart. The amount of

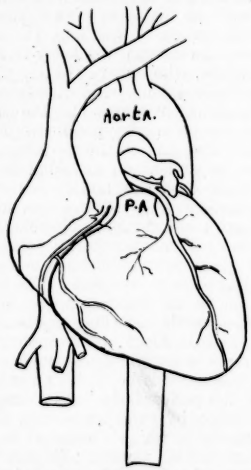

FIG. 5.— Heart from the front (from Quain).

the heart's bulk that lies to the right of the descending aorta makes it probable that any general pressure exerted on the heart would tend to thrust it *en masse* to the right, flattening the arch of the aorta rather than reversing the heart and twisting the vessels. This is what happens in left-sided exudates. When the fluid amounts to about 1,000 cc. pressure is exerted on the heart lying in the pericardium and it is pushed to the right *en masse*. In so doing the apex is depressed and rotated forwards, the heart's shadow in the fluoroscope losing its triangular appearance and becoming simply a mass in the center of the chest, with nearly vertical sides. In two of my cases, where the heart had become retained by adhesions in this position, I have been able to see the shadow of the apex of the heart spring outwards and slightly upwards from the dense central shadow with each contraction of the heart. This showed that when the heart was the smallest it tended to return to its exact normal position.

The movement of the apex can be traced across the left chest by the cardiac impulse, and in large exudates it finally disappears under the xyphoid. Sometimes the apical impulse can still be felt in

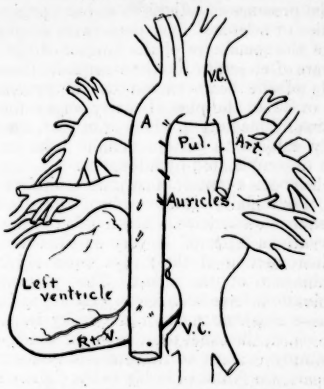

FIG. 6.— Heart from behind (from Quain).

epigastrium and the apical sounds can be distinguished with the stethoscope as being below the xyphoid.

At the same time that this is taking place on the left side of the chest, the movement of the basal mass of the heart brings the right auricle and the aorta closer and closer to the right thoracic wall, and cardiac impulse appears in the third space from the latter, and in the fifth or fourth space to the right, usually in or about the mammary line. Following one's first impression, that the place of the greatest cardiac impact and the loudest heart's sounds is the location of the apex, it has seemed to many clinicians that the apex in these cases of left-sided exudate was directed to the right, and at the place above stated. This too followed the teachings of Wintrich. The sudden deaths which have occurred in the course of pleurisy have been explained as due to the twisting of the great vessels, taking place in the inversion of the heart. This classic explanation has been followed almost implicitly in France, and as late as 1901 almost all the important text-books of medicine are credited by Alaux as having adhered to this teaching. In Germany, however, modern teachers for the most part have not taken this position, but have said that the heart was pushed or drawn to the right.

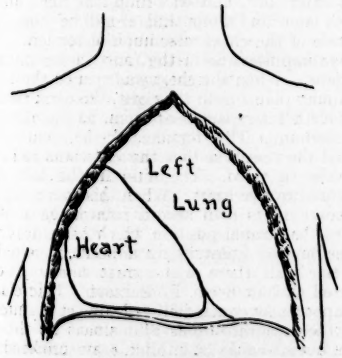
Professor Bard and others of the Lyons school have done much in France to call attention to the erroneous teaching, and as a result, for the past ten years cases have been reported which show more careful study than formerly and practically all of these have borne out the positions taken by Bard, Pitres and others.

In England, Powell as already said, from a large postmortem experience, recognized that it

was very rare for the apex to pass the sternum, and that the impulse seen in the region of the right nipple was always caused by the base of the heart.

Of the American teachers, Osler, as would be expected, makes the definite statement that he has never seen in simple effusions and pneumothorax the apex pointing to the right. Fitz speaks of the movement of the heart as a whole. Cutler in Loomis-Thompson sums up the whole question very neatly when he writes of " the cardiac impulse to the right, corresponding with the base and not the apex, the heart not changing its parallel." Musser and Eichorst also make correct statements. Cabot, Anders and Vierordt speak or give diagrams of the apex pointing to the right, and many of the other writers do not mention the matter at all.

As has been said above, the number of post-mortem examinations in cases of displaced heart is surprisingly small, and even when made the position of the apex is often not noted. Since the advent of the x-rays as an aid to accurate diagnosis many clinical cases are still reported, and in medical centers too, without any fluoroscopic examination to confirm the auscultation and general impressions. All the autopsies, however, that I have been able to find where any statement of the heart's position has been given, and all cases where the x-rays have been called into service, have (with a few exceptions to be noted later) shown the apex of the heart always pointed to the left.



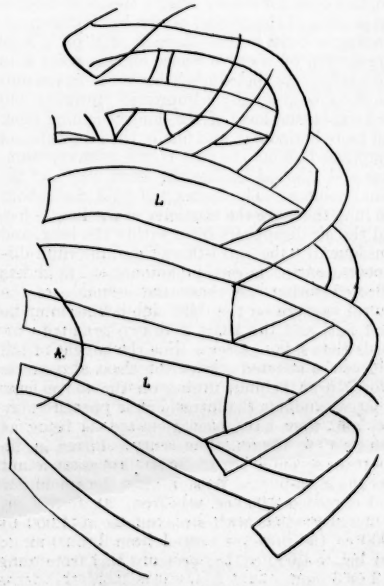


Fig. 7.— Garnier's case.

Carrière states that he has studied carefully with regard to the position of the apex twenty cases of left-sided pleuritis, and finds that in all there was no evidence of rotation of the heart. These observations have been supplemented by experiments upon the cadaver, and in none of these, as also in the experiments of Powell, Bard and Pitres, was there any sign of torsion even though the fluid put into the chest amounted to eight liters. The experiments and observations on pleuritic exudates made it seem that with about 700 cc. of fluid in the chest, the heart remains at its normal place if a vertical position is maintained, but that if the patient lies on the right side the heart's impulse moves from 2 to 4 cm. inwards. With fluid amounting to 1,000 to 3,000 cc. the apex becomes lowered and approaches the median line as described above, and as the fluid passes 2,500 cc. the apex passes beneath the xyphoid.

One of my first cases of displaced heart was a fine example of the fact that the base and not the apex gives the cardiac impulse on the right. The patient was a young girl with pulmonary tuberculosis of the right lung. The thin chest-walls made percussion very easy, and the house-officer who first saw her percussed triangular area of dulness on the right of the sternum which he called the apex. This was so distinct that he was not willing, in the light of his previous instruction, to acknowledge that it could be produced by anything else than the apex of the heart. However, the fluoroscope demonstrated the apex of the heart projecting just beyond the left border of the sternum, and the marked triangular dulness to the right was made by the base of the heart. The case was specially favorable to study, as the patient was a child, and then there was no thickened pleura and no exudate to obscure the field. The region about the heart was clear, so that the cardiac outlines were well defined.

In fluoroscopic examinations it must be borne in mind that a left-sided exudate will obscure the

Case of pneumothorax from the service of Dr. J. J. Minot. Left side of the chest. Traced from an x-ray photograph. A, shadow of the apex; L, compressed lung.

position of the apex, and that old pleuritic adhesions will cause such a shadow that the heart's position is often lost. But if there has been no disease upon the right side the general shape of the heart will show that the point of greatest impulse must be made by the base of the heart and not by the apex.

In an attempt to study the mechanics by which the heart is moved, it is well in the first instance to consider a pneumothorax. Here the air, gaining access to the whole pleural cavity, accumulates until the pressure within the cavity is equal or greater than the outside air. That this intra-thoracic pressure in the case of pneumothorax is great, there is no reason to believe. In the cases where the pressure has been studied, it has usually been from 3 to 7 cm. of water. In the single case I have had a chance to study the pressure has only been from 2 to 4 cm. of water, although in this case there was a marked displacement of the heart to the left. But to return to the mechanics of cardiac displacement: The left pleural cavity being filled with air, the lung is collapsed and the equilibrium previously existing between the two sides of the thorax is destroyed. There is now a vacuum-chamber only on the right side, and into that vacuum there is a tendency for the heart and its attachments to be both drawn and pushed, and unless hindered by adhesions it moves along the lines of least resistance already indicated.

Where an exudate is present the conditions are practically the same. As is well known, an exudate does not simply occupy the most dependent portion of the pleural cavity, but is drawn up, forming a layer on the thoracic wall on a level represented by a curve whose highest point is in the axilla. As the exudate increases in amount the lung is gradually compressed upwards and backwards, the level of the fluid becoming more and more horizontal, and finally the lung is found compressed about the root of the primary bronchus and jammed against the chest wall and the spinal column. The higher the fluid rises about the lung the more the elasticity of the lung is lost and the air disappears from within the lung, and consequently the intra-thoracic equilibrium disappears. After a certain amount of fluid has collected within the chest, the influence of the pleural vacuum on the right side begins to make itself felt, and the heart is drawn gradually towards that side. After a time the weight of the fluid in the affected side of the chest also exerts a force from behind, urging on the movement. In large exudates the intrathoracic pressure may rise, and they have been reported as being as high as 40 to 45 mm. of mercury. Pitres, in the reports of seventeen carefully studied cases, found that the intra-pleural tension when the amount of fluid exceeded 2,000 cc. was from 20 to 44 mm. of mercury; that with an exudate of 1,000 to 2,000 cc. the pressure ranged from 8 to 20 mm.; and below 1,000 cc. the pressure was from zero to 2 or 3 mm.

The amount of the pressure depends on a number of conditions, as for example if the diaphragm is weak and relaxed the amount of fluid may be large and the intra-thoracic pressure be small. On the other hand, with a consolidated lung the amount of the exudate may be small and the tension great.

The experiments in intra-thoracic pressure have been criticised by Bard as being inaccurate, from crude instruments and faulty technique, but as yet he had offered no accurate measurements, and what has been done may at least be accepted as showing approximately what takes place, there being practically the same element of error in all the observations. That there is intra-pleural pressure is obvious by the broad and even distended intercostal spaces which are frequently seen in large effusions. This pressure acts to give an accelerating push in addition to the suction exerted by the vacuum of the other side.

All those who of late have attempted experiments with the injection of fluids into the chest have been unable to produce any eversion of the heart, although very large amounts, even up to eight liters, have been used. Thus, Carriére, Pitres and Bard have maintained, reasoning from their experiments, that the rotation of the heart was impossible under any conditions. In addition, however, to the cases with adhesions or extensive right-sided effusion, already quoted, there has recently appeared a most interesting report by Lafforgue of displacement of the heart to the right, with inversion of the heart and bending of the great vessels. The case occurred in Algiers, where a native was stabbed in the back just outside the shoulder-blade. He bled but little externally, and was found at his home a month later, and a month later still he died. The left side of the chest was much distended. The cardiac impulse was in the fourth interspace to the right. When the chest was opened the heart was found pointing to the right, the apex behind the fourth interspace 3 or 4 cm. to the right of the sternum. The torsion of the heart had twisted the vessels so that the aorta was reduced in caliber a third. The fluid in the left side amounted to five liters. When this was removed the heart of its own accord rotated backwards toward the normal position, but was held at the border of the sternum by adhesions. On the posterior wall there was a firm fibrinous clot reported as 7 or 8 cm. in diameter. Here is a case apparently contradicting all the experiments and other accurate observations that have been made, but its cause is, I think, easy to interpret. The man bled profusely into the pleural cavity after the wound, and the large thick blood-clot must have pushed the heart upwards and held it there. Then as the immense exudate formed, it acted on an already displaced heart in such a way as to produce the torsion of heart and vessels.

In the third condition of displacement — when either there is a large cavity within the lung, causing a collapse of the surrounding wall, or any other cause, as syphilis, leading to a contraction of the lung tissue — there is left a void, and into this the organs of the sound side are aspirated. The heart passes into this cavity *en masse*, and greater

space consequently is given to the un-diseased lung which in turn takes on a compensatory hypertrophy, or emphysema. Special examples of this are to be seen in the diagram of Garnier's case and in the report of Fitzgerald and Everett's case quoted above. The movement of the heart in such cases as has been stated is often modified and accelerated by the presence of adhesions of the pleura of the shrunken lung to the pericardium.

Permanent but partial displacements of the heart are to be accounted for by the formation of adhesions to the pericardium before the heart has a chance to return to its normal position and are due to the slow absorption of the fluid.

In conclusion, it is to be remembered that in cases of displacement the heart tends to move as a mass to the right or left; that rotation is very rare, and accompanied when found by exceptional conditions, or brought about by the presence of contracting adhesions; that practically in all cases the visible cardiac impulse to the right of the sternum is caused by the base of the heart, and not by the apex; that extreme displacement may take place without the slightest discomfort to the patient; and that the sudden deaths occurring in the large pleuritic effusions are not due to the cardiac displacement.

The work of the coroner in Philadelphia for 1903 exceeded that of any other year in the history of the office. The number of inquests was 3,357—553 more than last year. There were 58 homicides, 202 suicides, 94 deaths by drowning and 932 casualties. Among the latter were 254 on steam and electric railways. — *Medical News.*

INTERMITTENT HYDRONEPHROSIS — UTERINE FIBROID.[1]

BY M. H. RICHARDSON, M.D., BOSTON.

INTERMITTENT HYDRONEPHROSIS.

My first operation for intermittent hydronephrosis was performed on Nov. 11, 1896, and was published in the Transactions of the American Surgical Association for 1897. I showed this patient before the Clinical Society of the Massachusetts General Hospital and before the Massachusetts Medical Society in 1897. The operation, which I called ureteroplasty, corresponded in principle to the Heinecke-Mikulicz operation for stricture of the pylorus. The junction of the ureter and the dilated renal pelvis was incised longitudinally, and this longitudinal incision was sewed into a transverse line. The effects of the kink or sharp bend at the origin of the ureter was thereby overcome. In my first patient absolute cure followed.

I found this route for exploring the pelvis of the kidney so easy that I have used it a number of times since in preference to the usual one of going through the cortex for renal stone or for other reasons. The practicability of plastic operations upon the pelvis of the kidney and upon the beginning of the ureter was thus made apparent to me by a considerable number of explorations.

My second case of intermittent hydronephrosis is the one shown here to-night.

Mr. L. N. I., twenty-three years of age, machinist, came to see me on July 14, 1902, sent by Dr. Averill of Brockton. For six months he had had pain in the left side about two inches below the ribs. The longest time that he had been without pain was eighteen days. The pain was sharp in character, lasting for twenty-four hours, and sometimes for longer. He had been completely disabled for some six months.

I found a large, tender mass in the region of the left kidney. It was impossible to say whether the tumor was fluctuating or not. Examination of the urine was negative. At the beginning the temperature was normal. At my first examination the tumor seemed to me to be the spleen, and I supposed the case one of a splenic leukemia. Examination of the blood, made by Dr. Williams, showed nothing but a leucocytosis. Five days later the mass had entirely disappeared. The patient himself had noticed nothing wrong with the urine. There were no constitutional symptoms at any time.

On Oct. 13 I again saw this patient. The history during the summer had been about the same as before. I found in the left renal region a tumor which was without doubt a kidney, and I at that time advised an exploration. The diagnosis was intermittent hydronephrosis.

The operation was performed at the Deaconess Hospital on Oct. 16, 1902. An incision six inches in length was made, starting from the ribs over the site of the tumor and running downward and forward. Throughout this incision the external and internal oblique and transversalis were separated in the direction of their fibers. The peritoneal cavity was opened sufficiently for a thorough exploration of the right kidney and the other abdominal organs. The opening in the peritoneum was then sutured, and the left kidney examined. Though the pelvis of the left kidney was much enlarged and much thickened, it contained no stones. The diagnosis was clearly hydrone-

[1] Read at the Boston Society for Medical Improvement, Nov. 18, 1903.

phrosis, caused by a sharp bend in the ureter at its origin at the pelvis of the kidney. A careful dissection was made of the renal pelvis and of the ureter, to show exactly the relation of the parts and the cause of the obstruction. An incision about an inch in length was then made extending through the pelvis of the kidney and extending down half an inch on to the ureter. The middle of the incision corresponded to the sharp angle of continuity between the pelvis and the ureter. This longitudinal slit was converted into a transverse one by appropriate sutures. A small wick was placed at the line of suture on the left.

The patient made a good recovery, and in a month was entirely healed and perfectly well. He was able to return to his work.

In April he was taken with a severe attack of appendicitis, for which he was advised by Dr. Williams. It was very evident that the trouble was in the appendix. On June 4, 1903, I removed the appendix through an incision an inch and a half in length. Since that time he has been perfectly well.

The operation for hydronephrosis was a very successful one technically, and it has resulted in perfect relief to the symptoms. Whatever may have been in the very beginning the cause of the obstruction, the result was a kink-like or valve-like origin of the ureter. Once the obstruction became sufficient to cause dilatation of the pelvis of the kidney, then that obstruction became more and more complete, the distended pelvis increasing the sharpness of angle and pressing directly upon the ureter.

This origin is, perhaps, somewhat a matter of theory. If the obstruction is caused, or is continued, by the pressure of the dilated pelvis upon the ureter, it is hard to say how the distension is ever released spontaneously, for the pressure needed by the dilatation cannot but increase. In this case, as in the previous one and in the following one, the hydronephrosis was intermittent — a distension of the pelvis of the kidney attended by severe pain. This pain continues more or less severe until the pelvis is excessively distended. Then, for some reason, the urine begins to flow, the pelvis is emptied, the pain and the tumor disappear.

CASE II. The next patient whom I show here, a brother of the last one, has symptoms which are very much like those already related. This young man is twenty years of age. He has had in the region of the left kidney for five years what he calls "side-ache." The pain comes on suddenly and is followed by vomiting. At times he notices a swelling at the site of the pain, "as if the ribs were pushed out some." The pain is described as a heavy, continuous one.

This patient came to me on Aug. 29, 1903, saying that the last attack had begun twenty hours previously. It began suddenly and it ended suddenly. He does not have the pain all the time. Sometimes it comes every month; then he will go for weeks without any. He has noticed nothing abnormal about the urine, except that after the cessation of the pain of the last attack he passed more than usual; he has never noticed any blood; and there has been no retraction of the testicle.

The physical examination was negative; also the examination of the urine.

His next attack was in October. It was like the others, but not so severe. I found tenderness in the region of the spleen and in the greater curvature of the stomach. After careful study of this case Dr. Joslin made a diagnosis of intermittent hydronephrosis.

The last attack was a week ago. The patient came to see me during the attack. He was suffering great pain. I was unable to make out any definite signs. In this case the diagnosis depends upon the history, with intermittent tumor. The symptoms seem to me to justify exploration of the kidney, which exploration I shall make day after to-morrow.

FIBROIDS.

The danger of malignancy a strong indication for the removal of supposed uterine fibroids. — In the early days of uterine surgery the dangers of removing uterine fibroids were so great that we very properly hesitated to advise their removal, except for certain definite indications, such as pain, hemorrhage, rapid growth and pressure. There are many fibroids which neither grow rapidly nor cause pain, bleeding or pressure. In other words, they present none of the ordinary indications for operation; and in the earlier days, no such tumors would have been removed. The chief reason urged against the extirpation of uterine fibroids, or supposed uterine fibroids, was the danger of the operation. At the present time the danger of hysterectomy has been reduced far below the danger of the original operations for ovarian tumors. Practically all hysterectomies for uncomplicated fibroids prove successful. The mortality in the hands of experienced surgeons is about as low as mortality can be in any severe operation, whether performed in the abdomen or elsewhere. True, the safety of the operation is very largely influenced by the experience and skill of the operator. Indeed, I believe that there is no abdominal operation in which the result depends more upon careful asepsis, clean and swift dissecting, rigid hemostasis, and painstaking avoidance of the ureters. The uncomplicated hysterectomy in a strong woman of child-bearing age is certainly as safe as the normal childbirth — always, be it understood, in the hands of an experienced surgeon. Now that the mortality has been brought so low, it is evident that the range of indications is correspondingly widened. When the risks of a hysterectomy were deemed justifiable only in certain grave symptoms, then the dangers were naturally great. Now that the dangers are small, the indications should include symptoms of minor severity and of less danger to life and to health. One of the dangers — and one never seriously considered — is the danger of a wrong diagnosis. I have seen too many errors in diagnosis, even in the hands of the most experienced clinicians, to be willing to accept as final, without exploration, the diagnosis of even the most skillful. I look upon all pelvic tumors as being possibly malignant. It is true that in the great majority of cases a correct diagnosis can be made, and is made. It is quite as true, however, that in the minority of cases the diagnosis is not made and cannot be made. Has not the time come, in the treatment of pelvic tumors generally and uterine tumors in particular, when the danger of overlooking a possible malignancy vastly outweighs the danger of exploration? In other words, are we justified in the palliative treatment of pelvic tumors, even when

they are apparently benign, knowing the great difficulty — not to say the impossibility — of an absolutely accurate diagnosis?

Case I. I have two specimens to illustrate the importance of this subject. The first was from a patient of forty-nine who had been under observation for four years for a uterine fibroid about as large as a Florida orange. This patient had passed the menopause two years. On account of pain and flowing, operation was finally decided upon. I operated upon this patient on Oct. 24, 1903. The uterus contained a single fibroid about the size of an orange. In the lower segment of the uterus, about the cervix, were numerous masses apparently malignant, encroaching upon the uterine cavity and extending beyond the uterine tissues into the layers of the broad ligament. These masses were apparently entirely removed. Dr. Whitney pronounced the disease to be a uterine fibroid with extensive sarcoma.

I show the specimen and also the drawing by Mr. Aitken.

Now this patient was very properly watched and cared for during and through the menopause under the diagnosis of a simple fibroid. It was not, however, a simple fibroid; —it was a complication rare, it is true, but of the most serious nature. Although there had been every reason to think that this was a simple fibroid, it nevertheless had a malignant and almost hopeless complication.

I have seen a number of cases of uterine fibroid either associated with cancer of the cervix or complicated by malignant degeneration of its own tissues.

Case II. The next specimen is from the case of Mrs. O., a woman of seventy, a patient of Dr. Cook of Fitchburg. Four years ago this patient began to flow. The flowing would last for a month, say, and then stop. The pain, hardly worth mentioning at first, gradually became more frequent and more severe. The general condition was good.

I found a uterus enlarged to the size of an orange and filled with small fibroids. Abdominal palpation showed a tumor over the vagina like that of an anteflexed uterus, filled with small nodules, — the whole suggesting a bunch of grapes.

I operated to-day through the abdomen. By bimanual examination I could feel a mass of small tumors, intimately connected with the uterus and was almost sure that the whole was malignant. The uterus between my hands felt as if it were filled with fluid and with small hard masses. The feeling of fluctuation was, however, due to a large and very soft tumor, the remains of which can be seen in this specimen. The gross appearances of this mass seem to me rather in favor of a soft uterine polyp, a non-malignant growth; but I shall not be at all surprised to be told that the soft masses here are malignant and that the main body of the uterus is filled with fibroids. Whatever the microscope may show, this is a case in which the only possibility of cure lay in a total extirpation of the uterus.

It is only by the promptest surgical intervention that malignant tumors of the uterus permit radical cure. Whenever we postpone operation on uterine tumors — no matter how benign these tumors may seem — we are running a risk beside which the dangers of operation are but trivial. I have no hesitation in saying that the dangers of overlooking a malignant tumor — even in the hands of the most skillful and the most experienced abdominal surgeon — are much greater than the dangers of exploration are in the same hands, especially when the tumor is discovered in early middle life. The older the patient, of course, the more imperative is exploration, for the tendency to malignancy increases with age, just as, unfortunately, the dangers of operation increase.

SOME CASES OF INTUSSUSCEPTION.[1]

BY FRANKLIN G. BALCH, M.D., BOSTON,

Surgeon to Out-Patients at the Massachusetts General Hospital.

Dr. Edred M. Corner of London has published an article on intussusception in the November number of the *Annals of Surgery*, in which he writes at some length on the various forms which this obstruction takes. Among other conclusions he decides that the double intussusception is more common than the single. The ileo-colic colic variety occurs most frequently, the colic ileo-cecal variety being next in order. He considers the single ileo-cecal variety quite uncommon. In the hurry of operation in these cases it is not often observed which variety is present, and in the records of some of the cases which I have looked up, the variety of the trouble is not mentioned. As Dr. Corner's observation that the double variety is more common than the single one is not the generally accepted theory, it will be of interest to try to get more accurate information upon this point in future operations.

Personally I have operated for this condition but three times. One case has already been reported in the *Medical and Surgical Journal*. In that case the obstruction was wholly in the small intestine, and was due to invagination of jejunum into ileum. Fifty-six inches of necrotic gut were resected. The patient recovered.

The second case has not been previously reported.

I saw Edith F. in consultation with Dr. Arthur N. Broughton on the 30th of July, 1901. She was a baby of five and a half months, who had had acute symptoms for only ten hours. The mother said she had noticed a minute speck of blood several times lately, but there was no diarrhea, and the baby had been gaining steadily. The night before I saw the child she had seemed feverish and had cried a good deal as if in pain. At 3 A.M. she vomited. Later there was a large movement followed by two bloody stools. The large movement was offensive. The first part was constipated, the last part loose. When I saw the child at 1.30 she seemed in great shock. She was apathetic, with a weak pulse of 144 and a rectal temperature of 98·4. A mass could be felt below the umbilicus. A diagnosis of intussusception was made, and operation showed it to be of the enteric ileo-cecal variety. The invagination was readily reduced, partly by pushing the bowel up from the large intestine, and partly by traction on the small intestine. The end of the cecum had been invaginated, and the appendix was reddened, but not otherwise abnormal. It was not removed. A band of adhesions ran across the cecum. That was cut before it was observed just what its point of origin was, and search later to clear that doubt was impossible on account of the child's condition. The wound was closed by silkworm-gut sutures. Six days later the upper stitch cut out during a fit of crying. The bowel came out, but under ether Dr. Broughton replaced it, and drew the edges of the wound together with crepe lise and collodion. Recovery otherwise was uneventful, and the child is very well to-day. A striking thing about the operation was the fact that as soon as the invagination was reduced the condition of shock began to improve, and the child looked better when put to bed than just before operation.

Another case was operated upon at the Massachusetts General Hospital. Ralph E. F., six months old, was seen May 29, 1903, at 10.30 P.M. He then had a temperature of 101.5, a pulse of 158, and a white count of 48,000. He

[1] Read at the meeting of the Boston Society for Medical Improvement, Nov. 16, 1903.

had felt poorly for a week, but the acute symptoms dated only from the day before. There had been sudden severe pains with frequent vomiting, and on the afternoon of the second day, the vomitus had become brown. The bowels had not moved for forty-eight hours, except a small movement after an injection. The child looked very sick. Nothing was felt by rectum. The abdomen was slightly distended, but not tender except over a tumor in the right side. There was considerable free fluid in the abdominal cavity. On opening the abdomen, several ounces of clear, slightly brownish fluid welled up. An intussusception was found in the ileo-cecal region, but the exact variety is not noted in the record. The bowel was dark and necrotic, so a mass about six inches long was resected. The ends were brought together by a continuous catgut suture, and a second layer of Lembert sutures, also of catgut, was placed outside. The mesentery was closed by an over and over suture of catgut. This controlled the hemorrhage very rapidly and effectually, while at the same time it approximated the cut edges. The patient never rallied after the operation, and died in about seven hours. An examination of the anastomosis after death showed a perfectly tight joint.

Since 1897 there have been ten cases of intussusception at the Massachusetts General Hospital. One of these was apparently reduced during the motion incident to bringing the child to the hospital, and making the necessary examination. The symptoms had been typical, and there was a tender tumor in the region of the cecum when the child was examined. This tumor also disappeared.

The other nine cases have all been operated upon. Three of the nine patients operated upon were over twenty-one years of age. Two of these recovered and one died.

Including my two cases which were operated upon outside the hospital, we have a total of eight cases in children. One of these was sixteen years old, and another three years old. Both lived.

In three of the cases that died resection was done. In one an artificial opening was made into the bowel, as the intussusception extended through the whole of the large intestine and could not be reduced. The fifth case died after the bowel had been reduced after opening the abdomen. In the one case that lived the invagination was reduced at operation.

As far as it is possible to draw any conclusion from such a limited number of cases, it would seem that the mortality decreases rapidly with the age of the patient. In children under one year of age intussusception is usually fatal. Very early operation offers the best chance of recovery.

THE BICYCLE AS A THERAPEUTIC AGENT.

LUTHER HALSEY GULICK, M.D.,

Director of Physical Training of the Public Schools in the City of New York; Secretary Public Schools Athletic League, New York City.

FEW cases are more exasperating than those which, without organic disease, are constantly demanding treatment for either real or imagined functional disorders, nor does it make much difference whether the disorder is in the realm of the so-called real or the imaginary. In either case it demands and deserves treatment and cure. A diseased imagination is as potent a cause of disease as a colony of pathogenic bacteria! It may be, indeed, far less susceptible to treatment.

Many of these cases present similar conditions — muscular weakness, ill-defined pains in the back and shoulders, inability to sleep satisfactorily, digestion uncertain, general feeling of worry and depression.

The general indication is for an increase of vigor, of vitality, something that will increase cell metabolism. Strychnia is temporarily effective in many of these cases, but inasmuch as the general conditions of environment remain the same, the patient soon reverts to the unsatisfactory state obtaining on beginning treatment. The agent which meets the conditions presented both theoretically and practically is muscular exercise. By this means, in many cases, the power of the digestive processes can be increased, general muscular tone secured, refreshing sleep and resulting wholesome view of life restored.

Muscular exercise of a general character is frequently prescribed, but often without beneficial results. The form of administration, the size of the dose, the frequency of the dose, and the psychic accompaniments of the exercise each form necessary elements for consideration. Success will depend upon good judgment on each of these points.

In order to secure the general organic effects of muscular exercise it is important, indeed it is well-nigh necessary, that the exercise involve chiefly the large muscular masses of the body. It is true that considerable quantities of energy can be expended by the smaller groups of muscles. One may exercise with the arms alone so as to secure genuine muscular fatigue, but the amount of neural expenditure involved, in order to secure the desired physiologic results, is far greater where the muscles are small than where they are large. To raise the weight of the body one foot, by means of the arms alone, involves expenditure of as many units of energy as is represented by the weight of the body. A person weighing 150 pounds would expend 150 foot-pounds of energy in raising the weight of the body one foot, whether this were done by the arms or by the legs. The sum total of the effect of this exercise upon the heart and lungs and digestive processes would not be essentially different in the two cases, for the organic effects are directly related to the number of foot-pounds of energy expended, rather than is the consciousness of fatigue involved. Where, however, the exercise is done with the legs, it is done with ease; when it is done with the arms it is accomplished, by women at least, with the greatest difficulty. The amount of will, and indeed of nervous energy, varies greatly in the two cases. A person who has by dint of great effort raised the weight of the body by means of the arms will usually find that when the hand is held free the fingers will tremble,

indicating overexpenditure of effort. The same amount of work done by the legs will not leave the individual in this undesirable condition. Thus, my first point in the use of muscular exercise as a therapeutic agent in the cases under consideration is that it should be primarily exercise of the large muscular masses of the body as distinguished from the small muscular masses. Such gymnastics as involve primarily movements of the arms are of slight value from the organic standpoint as compared with those in which the body itself is moved by means of the legs. In bicycle riding we find the work done by the large muscles. The muscles around the shoulder girdle are not exercised to any great extent, but all the muscles attached to and descending from the thorax to the pelvis, practically all the muscles connecting the pelvis with the thigh and leg are constantly involved in bicycle riding. This explains why it is so comparatively easy to affect the appetite, the sleep, the general circulation and respiration by means of bicycle riding as compared with the formal gymnastics usually employed. By means of the bicycle we expend many foot-pounds of energy without great neural exhaustion.

In order to the economy of nerve tissue, it is also important that the size of the load given to the muscular masses shall be small in proportion to their strength. The sum total of force expended in lifting one pound one foot for fifty consecutive times is identical with the amount expended in raising a fifty-pound bell one foot once. The neural results are, however, wholly different in the two cases. In the one case there has been little, if any, conscious effort; the work is done easily. In the other case it is only by great effort that the work is done; there has been strain of will and concentration of effort. The one form of exercise makes for nervous exhaustion, while the other does not. This principle of dividing the dose in those cases in which the effects of muscular labor are to be secured with a minimum of neural expenditure is fundamental in all these cases. We have no other agent by which we secure so readily a large number of minimum contractions of large muscular masses as we have in the bicycle. In ordinary riding on a country road, or a city street, each push upon the pedal involves but slight effort, but the sum total of work done, because of the large number of efforts, is very great.

A third element of great importance is that the conscious attention and deliberate exertion of the will shall be minimized; in other words, it shall be desirable that so far as possible the exercise be automatic. The illustration of the comparative ease of walking on a smooth road where the steps may be automatic, and the fatigue involved in walking railroad ties where the steps cannot be automatic, is familiar. The one demands constant attention, the other is done automatically. Our sense of fatigue is usually from central exhaustion, not from fatigue of muscle. Those activities which are presided over by automatic centers are far less liable to produce fatigue than those which demand conscious attention. Bicycling, after it has become familiar, thus corresponds to this indication. The riding and steering is wholly automatic. The completion of each revolution of the pedals itself acts as a stimulus to the impulse necessary in order to the next revolution. Amounts of work are done because of this automatic nature of the exercise, which would completely exhaust the patient if each effort were directed by the conscious will.

In regard to the psychic accompaniments of the exercise much might be said. The scientific data are not available which completely explain the differences between the effects of exercise when done alone and when done with pleasurable companions. It is probably due, however, to the increase in circulation which always accompanies the pleasurable emotions. If we accept the Lange-James theory of the emotions, we have a working hypothesis of great interest. Whether we have any hypothesis or not, the facts remain that muscular exercise under conditions of pleasant psychic associations has greater beneficial results than where other conditions prevail. The particular group of cases under consideration in this article demand diversion. It is but rarely that they can be persuaded to take systematic exercise for any considerable length of time, unless this exercise is made interesting to them. Gymnastic exercises taken alone, in one's room, are rarely, if ever, interesting, and while they are valuable in many cases, in this particular group they have proved, in my own hands at least, comparatively ineffective. In bicycling, bowling, golf, and such sports, I have found for these cases the well-nigh necessary pleasant associations; but in bicycling alone do we find both the physiologic and psychic conditions adequately met.

The fact that the exercise is taken out of doors is another point in its favor, for but rarely are rooms so well ventilated as to be as perfect in this respect as the country air. Then again, the direct effect of sunlight upon the tissues is secured out of doors and not indoors.

One of the immediate results of bicycle riding is a large increase in the respiration. Each excursion of the diaphragm is far greater than under conditions of quiet. Each minute includes many more respirations than when the individual is not doing muscular work. The effects of these respiratory movements upon the viscera constitutes one of the important beneficial results of the exercise. All those organs below the diaphragm, which include in their circulation the second set of capillaries, depend largely for their circulation upon other forces than that of the cardiac contraction. The alternate pressure and relaxation which the diaphragm exerts upon the liver is a large factor in promoting the various circulations within that organ.

Success or failure depends upon the accurate adaptation of the size of the dose to the individual need. Many of these cases have hearts that are weak. Upon moderate exertion they will

often run up to 120, or even higher, per minute. In these cases, in my own practice, the rule is to take the heart as a guide, and to increase the size of the dose with the increase of cardiac power. I determine the size as follows: Assuming that the patient already knows how to ride, I have him ride at the ordinary rate of speed for five minutes; I then count the heart rate and note its power. If the rate is below 100 I continue for another five minutes and count again. If several such periods of work fail to increase the heart rate above 100, I conclude that the heart is thoroughly able to take care of the work imposed upon it at this rate of speed. I then direct my attention to other considerations. If, on the contrary, at the end of the first five minutes I discover that the heart has run up to over 100, the patient must either then sit or lie down for five minutes. If after five minutes' rest the heart has not gone down to between 70 and 80, it indicates that the heart has done more work than its present degree of strength will warrant it in doing. No further exercise should be given until the heart comes back to approximately its normal rate. Even five minutes of exercise may produce genuine cardiac fatigue in a very weak heart, which may persist for hours or for days. One spring, when I was not in good condition, I played five tennis sets successively with great vigor; it was thirty-six hours before my heart got below 85. The only way to judge in these cases as to what is safe to give the heart is by proceeding cautiously and testing it at frequent intervals. The case is rare, however, in which five minutes' gentle exercise will not completely recover within five minutes' rest. This small dose may almost invariably be repeated for three or four times, the few minutes' rest always intervening. Gradually with the increased strength of heart, the periods of rest may be made shorter, the periods of riding longer, and ultimately the speed of riding somewhat increased. It is, however, never wise, for therapeutic purposes, to ride at a rapid gait, for here the expenditure of nerve tissue in order to stimulate the muscles to greater activity is much greater in proportion to the work done than where the ride is at a moderate gait.

In those cases in which the heart, as shown by the preceding test, is fully competent to meet the work demanded, the test of fatigue is the movement of the fingers when the arm is held extended from the body with the fingers spread. The fingers and hands should be as steady as they are during ordinary daily conditions. As soon as the fingers begin to tremble or to make athetoid movements, the demands upon the nervous system have been greater than is desirable; hence the stimuli to the muscles are not regular, hence the trembling. The doses of exercise should be so divided that this trembling will not be produced.

The patient who could not possibly stand fifteen minutes of vigorous exercise consecutively given, because of weak heart or an exhausted system, will readily endure with advantage fifteen minutes' exercise divided into three doses, with five minutes' rest between each dose. This may be repeated with ease twice or three times, and under certain conditions four times during the twenty-four hours. I have seen patients under this treatment have long quiet nights of sleep, with appetite that began to increase within two or three days, who thought that they were utterly unable to take exercise.

The third guide with reference to the size and frequency of the dose is as to recovery over night. Fatigue should never be allowed to become consecutive. Each night should see complete recovery from the fatigue of the preceding day. This must not be understood to mean that a person who always rises with the sense of fatigue shall immediately upon the beginning of treatment lose this consciousness. It does mean, however, that this consciousness of fatigue should not be increased. In the course of two weeks to a month it should be wholly lost. If so much work is given that the morning fatigue indicates that there has not been complete recovery from the exercises of the preceding day, the result will consist in a gradual decrease in the vigor of the patient.

I have but one word to say in regard to the position on the bicycle. Aside from the proper adjustment of the saddle, the one other important point is that the spine shall not lose its normal relations. It is not of particular significance that the spine shall be erect or inclined forward, provided the spine itself be not bent in the dorsal or the lumbar regions. If the pelvis is tilted forward, the whole spine may be inclined forward at an incline of even 45 degrees without interfering in the least degree with the respiration or circulation; but if bending forward is accomplished by the bending of the dorsal and lumbar spine, the result is an embarrassment both of cardiac and respiratory activity. Both the depth and the width of the thorax are decreased. The heart becomes irregular because of the restricted chest when it would not do so were it not embarrassed by the position of the thorax. The height of the handle-bars thus has comparatively little to do with the wholesomeness or the unwholesomeness of the position. The fundamental question is, is or is not the spine bent?

A small caution needs to be given at this point. In learning to ride we have a new element introduced, we have the acquirement of a habit involving a somewhat complex set of muscular co-ordinations. This is in itself a considerable demand upon the nervous system, so that if the patient has to be taught to ride it should be done with slowness. It may easily increase nervous fatigue and exhaustion.

To summarize, the bicycle is a useful therapeutic agent in those cases in which it is desirable to quicken the general organic functions of circulation, of respiration, of the whole digestive tract, together with ample diversion and out-of-door air. Its particular advantages are that it gives exercise of the large muscular masses, that

the exercise consists of a great number of small efforts; that it is automatic and does not call for great neural expenditure, in proportion to the amount of work done there is but little consciousness of fatigue; that the exercise is out of doors; that it is available anywhere; that with it there may be good companionship and varied scenery.

MERCURIC CYANIDE AS A SURGICAL DISINFECTANT.

BY CHARLES HARRINGTON, M.D., BOSTON,
Assistant Professor of Hygiene, Harvard Medical School.

In the course of a series of experiments in the field of practical disinfection, I turned my attention to the determination of the rapidity of action of mercuric cyanide, a substance which of late has come into considerable favor in surgical practice, being used in solutions of 1-1000 and 1-2000 as a substitute for corrosive sublimate, over which it is believed to possess a number of distinct advantages, among which are non-formation of precipitates with albumins, and rapid action. The latter quality is certainly of the very greatest importance, since an agent that destroys bacteria only after prolonged contact may be worse than none at all, because of its leading to a false sense of security. Thus, with full confidence of immediate action, one may proceed in an operation with an agent that serves no useful purpose.

In testing the germicidal property of mercuric cyanide, silk threads impregnated with twenty-four-hours-old bouillon cultures of *Bacillus pyocyaneus*, *Bacillus coli communis*, and *Staphylococcus pyogenes aureus* and *albus* were subjected to the influence of a 1-1000 solution of the pure salt. After varying periods of contact, they were withdrawn and planted in tubes of sterile bouillon, which were then incubated at 37° C. for twenty-four hours. In the first experiment, the longest period of contact was ten minutes. The table below, in which + indicates growth and — indicates sterility, sets forth the results.

Exposure.	B. Pyocyaneus.	B. Coli.	Staph. Aureus.	Staph. Albus.
10 seconds	+	+	+	+
30 "	+	+	+	+
30 "	+	+	+	+
40 "	+	+	+	+
50 "	+	+	+	+
60 "	+	+	+	+
1½ minutes	+	+	+	+
2 "	—	—	+	+
3 "	—	—	+	+
4 "	—	—	+	+
5 "	—	—	+	+
7 "	—	—	+	+
10 "	—	—	+	+

The results obtained with the two species of pus cocci led to further experiments to determine how long these organisms can maintain their resistance. *Staphylococcus albus* survived exposures up to twenty-five minutes, but was destroyed in half an hour; *Staphylococcus aureus* was unaffected by contact for no less than three hours. The threads infected with this organism were exposed 10, 15, 20, 25, 30, 35, 40, 45, 50, 55 and 60 minutes, 1½, 2, 2½ and 3 hours, and with the exception of the last, which required 48 hours' incubation, all yielded abundant growths within 24 hours.

Mercuric cyanide is more commonly employed in conjunction with double its weight of borax, which substance serves to prevent corrosion of instruments. Since the combination might, perhaps, prove to exert a more pronounced bactericidal influence than the cyanide alone, it, too, was given a trial. Prepared tablets, one of which in a liter of water gives a cyanide strength of 1-2000, were obtained, and two solutions were made: one with 4 tablets (1-500) and the other with 1 (1-2000). Neither proved to have any influence whatever on *Staphylococcus aureus* up to a half hour, beyond which time the tests were not continued.

The above results can lead to but one conclusion concerning the practical value of mercuric cyanide, for a substance which, when employed in the strength recommended, cannot destroy all known species of pus organisms within three hours, and in double that strength accomplishes nothing in thirty minutes, can hardly be classed among the efficient germicides.

Medical Progress.

REPORT ON PEDIATRICS.

BY THOMAS MORGAN ROTCH, M.D., AND JOHN LOVETT MORSE, M.D., BOSTON.

AN ANATOMICAL STUDY OF THE GASTRO-INTESTINAL TRACT OF INFANTS.

Bloch [1] studied the stomachs of 5 infants that died of other than digestive troubles, and the intestines of 9 normal infants, and of 10 dead of gastro-enteritis. He injected from 100 to 150 cc. of a 10% solution of formalin into the peritoneal cavity immediately after death. In this way he obtained very satisfactory specimens.

He found that in the stomach the number of glands per unit of surface was somewhat less than in adults and that their arrangement was irregular, the glands being grouped. The glands in infants were much smaller and contained much fewer gland cells. The glands were, however, of the same sort as in adults and the gland cells were as well developed. The functions of the glands and of the cells were equally well developed We must believe, therefore, that the gastric juice of infants contains the same ferments as that of adults, but that in the first few months it is feeble both in ferments and in hydrochloric acid.

While the mucous membrane of the stomach in infants is but little developed, the mucous membrane of the intestine is, on the other hand, developed to the highest degree. Almost the same number of glands and villi per unit of surface are found in the intestine of the infant as in the adult. They also are nearly of the same size. The superficial epithelium is also as well developed in infants as in adults. He recognized two sorts of Lieberkuhn's glands, one secreting only mucus

[1] Jahrb. f. Kinderheilkunde, 1903, v. lviii, p. 121.

and one a special intestinal ferment. He found these latter glands throughout the whole small intestine, as in adults, and also in the upper two-thirds or three-quarters of the large intestine. Those in the large intestine gradually diminished in number and had disappeared at two years. The mucous glands, as in adults, were found only in the large intestine.

While the mucous membrane of the intestine is developed to a very high degree in infancy, the other intestinal layers are less developed. The slight development of the muscles of the intestine is especially striking. Both the circular and longitudinal muscles form only thin layers in the intestine of the infant. He found as the average figures of a number of measurements of the equally contracted parts of the jejunum thickness of the mucous membrane in adults .20; in a two months' old infant .18; thickness of the muscular coat, adults .90; two months' old infant .35. His investigations showed conclusively that the muscles were not much stronger at ten months, but that by two years they were decidedly stronger, although not as strong as in adults.

The intestine of the infant is proportionately much longer than that of the adult. This is probably principally due to the slight development of the intestinal muscle. For this reason the valvulæ conniventes and the cross folds in the mucous membrane are less in number and smaller in size. Even if the intestine of the infant is relatively longer than that of the adult it does not follow, however, that the surface of the mucous membrane is relatively greater in the infant.

A STUDY OF GASTRO-INTESTINAL CATARRH IN INFANTS.

Bloch[2] reviews the literature on the subject and then gives the results of his own study of ten cases of gastro-intestinal disease in infancy. The intestines were hardened by the injection of a ten per cent solution of formalin into the peritoneal cavity immediately after death. In this way he prevented any post-mortem changes. His results differ materially from those of Baginsky and his followers in that the marked degenerative changes described by them were wanting. He believes that these changes which they described were post mortem in origin. He failed to find certain peculiar degenerative changes described by Heubner, Marfan, and others.

He concludes that there is an inflammation of the intestinal mucous membrane in the acute and chronic gastro-enteritis of infants which is most marked about the ileo-cecal valve. The more marked intestinal changes ordinarily extend but a short distance into the small intestine. The inflammation is more generally distributed in the large intestine. In individual cases a less marked inflammation may also occur in the duodenum, but by far the greatest part of the small intestine is free from marked inflammatory appearances. The superficial epithelium and the intestinal glands are for the greatest part well preserved.

Inflammation occurs in the intestine in the same way as in all other mucous membranes.

In the acute forms it shows itself especially by a marked injection, numerous hemorrhages and a slight round-cell infiltration of the mucous membrane. The glands may show cystic dilatation. A large part of the cells of the glands and of the superficial epithelium is destroyed in these places and hemorrhagic ulcerations occur.

In the more chronic forms are found the same changes, but less marked in degree. They are characterized by a marked round-cell infiltration of the mucous membrane and sub-mucosa and by an exudation of round cells. In addition, superficial losses of substance and follicular ulcerations are found.

A sharp differentiation between the acute and chronic forms is no more possible anatomically than it is clinically; they run gradually into each other.

In the stomach occur inconstantly hemorrhagic ulcerations and alterations in the interstitial tissue. The superficial epithelium is always well preserved and normal, and the glands usually so.

A STUDY OF THE INTESTINES IN INFANTILE ATROPHY.

Among other cases Bloch[3] carefully studied the intestines of three cases of atrophy. No noteworthy pathological changes could be made out microscopically. The intestine was long and its wall was thin as paper. Both conditions were a direct result of the distention of the bowel. The thinness of the wall is, he claims, certainly not due t an atrophy of the mucous membrane, but is merely a necessary result of the distention. Microscopically he found no important pathological changes, no destruction, no cicatricial changes and no extensive degeneration. The mucous membranes were everywhere well preserved with the epithelium, glands and villi of natural form and in normal quantity. No signs of inflammation were made out. The mucous membrane was, on the other hand, anemic and contained few leucocytes.

He also studied the various glands which secrete the ferments necessary for assimilation and absorption. The glands of the stomach showed no alterations, neither did the pancreas, Brunner's glands, or liver. Lieberkuhn's glands were well preserved in all cases and all had their natural form. This was not the case with the gland cells, however. The author studied especially Paneth's cells. In the cases of atrophy which he investigated these cells were either absent or very few in number. This happened only in the cases of atrophy and not in children with acute or chronic gastro-intestinal catarrh. In these Paneth's cells were always found.

It seems, therefore, that the diminution in the number of secreting Paneth's cells is peculiar to

[2] Jahrb. f. Kinderh., 1903, v. lviii, p. 733.

[3] Inaugural Dissertation, Copenhagen, 1902. Abstr. in Jahrb. f. Kinderh., 1903, v. lviii, p. 271.

infantile atrophy. Lieberkuhn's glands are, therefore, in these cases, not in a condition to perform their function as serous glands of digestion.

THE LEUCOCYTES IN THE SUMMER DIARRHEA OF INFANTS.

Zahorsky[4] examined the blood of 7 infants suffering from gastro-enteric infection, but without signs of colitis. He concludes that the leucocyte count in these cases is too variable to be of special diagnostic importance. He believes, however, that the differential count is extremely valuable in estimating the intensity of the intoxication. The normal ratio of the polymorphonuclear neutrophiles to the lymphocytes in infants is 2 to 3 or 4. In gastro-enteric disease this ratio is changed, the polymorphonuclear cells gradually increasing, while the lymphocytes diminish, the ratio becoming 1 to 1, 4 to 3, or even 3 to 1. A predominance of the polymorphonuclear forms is a corroborative sign of the intensity of the morbid process. A great relative increase in the polymorphonuclear leucocytes means that the baby is pretty sick, whatever the other signs may indicate.

(To be continued.)

Reports of Societies.

AMERICAN PUBLIC HEALTH ASSOCIATION.

PROCEEDINGS OF THE THIRTY-FIRST ANNUAL MEETING, HELD AT WASHINGTON, D. C., OCT. 26, 27, 28, 29, AND 30, 1903.

(Concluded from No. 1, p. 21.)

ON THE VALUE OF TESTS FOR BACTERIA OF SPECIFIC TYPES AS AN INDEX OF POLLUTION.

MR. H. W. CLARK and STEPHEN DEM. GAGE, Boston, Mass., in their joint paper with the above title said that the principal types of bacteria used as indices of pollution are the colon type, sporogenes type, sewage streptococcus type and occasionally the two so-called paracolon types, *i. e.*, the aerogenes or enteriditus Gartner type and the chologenes type. The colon type is the most numerous of these in normal sewage and is accordingly of the most value as a specific indication of pollution. Bacteria of the colon type can be detected in ordinary city sewage in dilutions of 1-10,000 to 1-100,000. The presumptive test as applied to the colon type, reacting as it does with some 58 well described species of bacteria, covers too broad a field unless followed by confirmatory tests. Tests for B. coli at the Experimental Station at Lawrence have agreed well with the results obtained by chemical analysis and by inspection of the sources of the samples.

Surface waters having the greatest relative population on their watershed have shown bacteria of the colon type more frequently than others with less population. Ground waters, on the other hand, unless grossly polluted never show bacteria of colon type. Samples of shellfish from sources polluted and unpolluted have almost invariably shown the presence of B. coli in the polluted samples and their entire absence in the non-polluted samples. Examinations for B. coli in different volumes of water show that tests in both 1 and 100 cubic cm. should be made, the tests in larger volumes being confirmatory of the tests in the smaller volumes; and in cases where a considerable number of samples are taken from the same source tests in the larger volumes usually give more information day by day as to the quality of the water than do the tests in 1 cubic cm.

Epidemics of typhoid fever coincident with the findings of B. coli in normally pure waters, *i. e.*, in waters known to be safe under ordinary conditions, but becoming dangerous by the accidental entrance of polluted water, have occurred within the observations of the writers, where, although the entrance of this pollution was known, the danger was not indicated by chemical tests or by an increase in the numbers of bacteria beyond the usual limits of variation for waters of this class. Comparative tests for the relative viability of B. typhosus and B coli show that there is a very great similarity between the length of life of the two germs under a great variety of conditions.

ISOLATION OF BACILLUS COLI COMMUNIS FROM THE ALIMENTARY TRACT OF FISH AND THE SIGNIFICANCE THEREOF.

MR. GEORGE A. JOHNSON, Poughkeepsie, New York, read a paper on this subject. He stated that it has been shown that the colon bacillus is taken up by fish, and the results of the experiment described indicate that it multiplies rapidly in the intestinal tract of the same. It has been shown that a search of a large number of fish caught in an unpolluted water failed to reveal the presence of this organism in the intestinal tract. It would seem possible, therefore, that fish, having taken up the colon bacillus from a polluted water might migrate to a water of comparative purity where they would naturally discharge the greatly increased number of these organisms. Whether the finding of the colon bacillus deposited in a water in this manner would depreciate the value of the colon test in the examination of a public water supply is a question. It would certainly appear that if the colon bacillus can be thus easily transferred from one water to another the transportation of the typhoid bacillus may be considered quite as likely. At least, the above results may explain the apparent phenomenon frequently noted where B. coli communis is found in comparatively large numbers in waters apparently open to but remote chances for fecal contamination.

THE BACTERIAL EXAMINATION OF ONE HUNDRED AND FOUR SAMPLES OF WATER, TOGETHER WITH A DETAILED STUDY OF THE COLON BACILLUS.

DR. WILLIAM G. BISSELL, Buffalo, New York, read a paper on this subject. In connection therewith he said that after consulting with many

laboratory workers it had been decided to inaugurate an investigation along the following lines:

First Division. To ascertain what constitutes a colon bacillus.

Under this division the following points were considered: (*a*) Isolation and culturing in the different media of colon bacilli from fifteen different sources.

(*b*) The comparison of colon bacilli so isolated with certain lactic acid organisms.

(*c*) A comparison of presumptive tests using colon bacilli and two organisms common to most waters., viz., the bacillus fluorescens liquefaciens and the bacillus putridus.

A recapitulation of the results demonstrated that the amount of gas produced, the production of indol and putrefactive odors are not constant factors with even true coli; that many of the lactic acid organisms bear a close resemblance to colon bacilli; and that it is not safe to depend upon presumptive tests alone in determining the presence of colon bacilli in the water.

Second Division. The amount of water advisable to test in arriving at an indicator of pollution: 104 samples of water coming from Niagara river were examined at respectively 12 and 22 miles below a place where the sewage of over 400,000 people is received. Different amounts of each sample were examined and the comparative frequency of the presence of colon bacilli determined.

A summary of the results demonstrated that colon bacilli were present in 52% of the samples when 1 cc. was the amount examined at the 12-mile distance and in but 34% when 1 cc. was the amount examined at the 22-mile distance. Both sides of the river are used for farming purposes. Many samples were collected during heavy rainfalls. A recapitulation tends to demonstrate: (*a*) That colon bacilli were not found in all cc. amounts of the sample.

(*b*) That there was a decrease in the number of colon bacilli, the greater the distance down the stream.

(*c*) That the heavy rains did not seem to increase the number of colon bacilli, although the land was used for farming purposes.

Third Division. A test was made as to the longevity of colon bacilli in natural water. Excrement from the horse, cow and from human beings were placed respectively in each of three wells. A test was made of each well at different periods. The results tended to demonstrate that colon bacilli can live in well waters at least one hundred and nine days, and that the human variety seems to have a greater resistance than that from other sources.

Fourth Division. Tests were made to determine the degree of frequency with which colon bacilli could be found in water known to be pulluted with sewage. The results obtained tended to demonstrate that not all cubic centimeter amounts of such samples demonstrate the presence of the organisms. The writer believed that many organisms have been mistaken for the colon bacilli in water work.

Fifth Division. Tests were made to ascertain the degree of frequency with which colon bacilli can be found in water not presumably polluted. This work was necessarily confined to well water. Results tended to demonstrate that there are many wells the waters of which do not contain colon bacilli, even though larger quantities are examined.

A SIMPLE METHOD FOR THE ROUTINE DETECTION OF COLON BACILLI IN WATER.

A paper on this subject was presented by DR. ROYAL STOKES, Baltimore, Md. This paper proposed the use of neutral red in a fermentation tube containing 1% lactose or milk sugar bouillon, for the routine detection of colon bacilli in drinking water. The work of Theobald Smith has shown that the colon bacillus ferments lactose with the production of from 30 to 50% of gas, that the medium is acidulated, and that the proportion of gas is usually that of one part of carbon dioxide to two of hydrogen. Jordan studied a large number of bacteria which carried out all of the phenomena in the lactose fermentation tube which is characteristic of the colon bacillus. The writer also isolated a moderate number of fermentive bacteria from the Baltimore water supply, and failed to find any fermentive bacteria exactly resembling the colon bacillus in lactose bouillon in the fermentation tube.

In addition to the above characteristics of the colon bacillus in lactose bouillon, this organism causes a characteristic color reaction when neutral red is added to the solution in the proportion of 10 cc. of a .5% solution to 1 liter. This has been partly described by Irons and others, but they use the test in an ordinary test tube.

When used in the fermentation tube, the open bulb remains a port wine color and the closed bulb a light canary yellow, often showing fluorescence. The curved stem joining the closed and open bulbs shows an abrupt contrast of the colors usually in the middle of the curve. The members of the proteus and cloacæ group usually turn both bulbs yellow, but not always.

The method recommended is to inoculate a fermentation tube containing 1% lactose neutral red in the routine examination of water. If the percentage and amount of gas, the acidity, and the typical yellow-red contrast reaction all occur, the organism can be considered as bacillus coli communis. This is a much shorter method than the isolation in pure culture which takes from five to seven days, and will also make it easier to carry out quantitative experiments. These four distinct characteristics would seem to be sufficient to identify the colon bacillus in simple routine work.

REPORT OF THE COMMITTEE ON THE SIGNIFICANCE OF B. COLI IN WATER SUPPLIES.

MR. S. C. PRESCOTT, chairman of this committee, said in substance that to present a statement of the opinion of the committee individually and as a whole as probably representing the generally

accepted views of sanitary bacteriologists as to the significance of B. coli in water, the following questions were sent to each member. The answers appended, except as otherwise stated, were practically as given below.

(1) In view of the fact that numerous investigators have found B. coli in nature where it could not be directly traced to sewage or fecal pollution, do you believe that the colon test of water is as safe an index to pollution as it was formerly regarded to be? *Yes.*

(2) Are you of the opinion that the number of colon bacilli rather than their presence should be used as a criterion of recent sewage pollution? *Yes.*

(3) To pronounce a water sewage-polluted, would you require as evidence that B. coli was present in a majority of one cubic centimeter samples? *Yes, in general.*

(4) Are you in favor of recommending that the examination of large samples for B. coli 100-1000 cc. be discouraged? Four members say in reply, *Yes.* One says, *No.*

(5) In case of a strong presumptive test, what confirmation tests would you require to make certain that the organisms present were B. coli? *Full set of distinctive cultural tests.*

(6) In view of the probable presence of streptococci in polluted waters, do you think it desirable that they be isolated as well as B. coli to confirm suspicious evidence of pollution offered by B. coli? Two could not recommend this; one thought it would be advantageous occasionally, but not practicable because of increase in routine work; one believed it should be done, when possible, for the sake of securing additional data, and for its general confirmation of the colon test; and one was indefinite.

MR. EARLE B. PHELPS read a paper on

A CRITICAL STUDY OF THE METHODS IN CURRENT USE FOR THE DETERMINATION OF FREE AND ALBUMINOID AMMONIA IN SEWAGE.

A DANGEROUS FOOD-PRESERVATIVE.

DR. CHARLES HARRINGTON, Boston, Mass., in a paper on this subject, stated that sodium sulphite is used very extensively as a food-presevative, and more particularly for its effect on the color of chopped meat (Hamburg steak) and certain canned vegetables (asparagus and corn). The assertion made in 1896 by Kionka that it is a dangerous mixture has been combated by a number of experimenters and reaffirmed by Kionka and Schulz. Dogs fed on meat containing 0.20% of the salt were found by them to present extensive lesions in almost every organ, while others fed in the same way by Lebbin and Kallmann showed nothing abnormal.

In this experiment, five cats were fed for five months on beef containing 0.20 % and a sixth one with untreated beef. All six began at once to gain in weight, but at about the ninth week all but the control began to lose and they continued to do so up to the twentieth week, when all were killed. The organs of the control were normal. The chief lesion observed in the others was a parenchymatous degeneration of the kidneys. Each of the five presented cloudy swelling and marked fatty degeneration of the renal epithelium. Acute interstitial nephritis was present in one case.

THE TERMINATION OF QUARANTINE IN DIPHTHERIA.

DR. T. W. SALMON read this paper, which had been written, he stated, because of the very great importance, in considering the duration of quarantine in diphtheria, of knowing just how long diphtheria bacilli persist in those who have had the disease, and of detecting what constitutes satisfactory evidence of their final departure.

One hundred consecutive cases of diphtheria which occurred at the Willard State Hospital had been studied with reference to these features. Any special interest or value in the review of these cases, said the writer, lies in the fact that all the individuals remained under close observation for months after their recovery, and that cultures were taken at frequent intervals from both nose and throat long after they had ceased to be infected.

The one hundred cases included those in which no pseudo existed and those of real severity. Several nasal cases were among them.

The cases were analysed in some detail in the paper and an effort made to show:

(1) In what proportion of the cases a single negative culture from the throat would have been satisfactory evidence of the disappearance of diphtheria bacilli.

(2) In what proportion of the cases two negative cultures from the throat would have been sufficient.

(3) In what proportion of the cases three negative cultures from the throat would have been sufficient.

(4) In what proportion of the cases cultures from the throat alone would have failed to reveal the persistence of diphtheria bacilli elsewhere.

The causes for failure to detect the bacilli when subsequent culture showed them to be present were briefly considered.

OFFICERS ELECTED.

President, DR. CARLOS J. FINLEY, Havana, Cuba; First Vice-President, DR. J. R. MONJARAS, Mexico, Mexico; Second Vice-President, DR. W. W. WOODWARD, Washington, D. C.; Secretary, DR. CHARLES O. PROBST, Columbus, Ohio; Treasurer, DR. FRANK W. WRIGHT, New Haven, Conn.

Havana, Cuba, was selected as the place for holding the next annual meeting.

THE scare occasioned in Lincoln, Neb., by the report that twenty-five cases of leprosy had been discovered in the Russian colony, has been dispelled by the report of the Health Commissioner, who made a thorough investigation. — *American Medicine.*

Recent Literature.

A Manual of Surgical Treatment. By W. WATSON CHEYNE, C.B., M.B., F.R.C.S., F.R.S., Professor of Surgery in King's College, London, Surgeon to King's College Hospital and the Children's Hospital, Paddington Green, etc., and F. F. BURGHARD, M.D. and M.S. (Lond.), F.R.C.S., Teacher of Practical Surgery in King's College, London; Surgeon to King's College Hospital and the Children's Hospital, Paddington Green, etc. In Seven Volumes. Volume VII. The Treatment of the Surgical Affections of the Rectum, the Liver, Pancreas and Spleen, the Genito-Urinary Organs, the Breast and the Thorax. Philadelphia and New York: Lea Brothers & Co. 1903.

This is the final volume in this work on surgical treatment. The series is eminently practical and we have but little doubt that these books supply a distinct need. One very encouraging thing has been that, as the work has progressed, its value has increased. One may differ from the views expressed by the authors, but the manual as a whole is distinctly of value. This volume deals with surgical affections of the rectum and anus, pancreas, liver and spleen, genito-urinary organs, bladder, prostate and urethra, of the penis, testes and scrotum, affections of the breast and affections of the thorax and its contents. It makes a relatively large volume of 550 pages and is fairly well illustrated. On the whole, we can recommend this series of volumes to surgeons. Many of the ideas are English, but, after all, there is perhaps no place in the world where patients are better cared for than in England.

Uterine and Tubal Gestation. A Study of the Embedding and Development of the Human Ovum, the Early Growth of the Embryo, and the Development of the Syncytium and Placental Gland. By SAMUEL WYLLIS BANDLER, M.D., Instructor in Gynecology, N. Y. Post-Graduate School. 93 illustrations. 159 pp. New York: William Wood & Company. 1903.

The author divides his book into three parts: Part I, The Essentials of Uterine Gestation; Part II, The Essentials of Tubal Gestation; and Part III, Ovarian and Placental Secretion.

In Part I the changes which take place in the uterus during menstruation are traced, and the statement is made that "Menstruation is not a process by which the mucous lining of the uterus is thrown off, with subsequent regeneration previous to the next menstruation. It is simply the excretion of blood from the decidua menstruatis occurring for the simple and sole reason that there is in the uterus no fecundated ovum." "Ovarian secretion is the direct cause of this periodical swelling of the mucosa, and it continues, if fecundation has taken place, to exert, not alone a local, but likewise a stimulating influence on the general and sexual organs."

The embedding of the human ovum is described in great detail and with the aid of numerous drawings, also the development of the ovum. The origin of the syncytium is discussed in detail and the view is held that it is probable that the placenta is a gland with potentials of great importance from the standpoint of secretion.

In Part II, under the heading of "Processes Antedating Tubal Gestation," it is found that external migration of the ovum occurs frequently in tubal gestation, and that inflammatory changes which are common as causative of ectopic gestation destroy the cilia in whole or in part or diminish their functional activity.

After discussing the various opinions as to the histological processes of tubal gestation the author concludes "that, with the exception of the absence of the decidua and an enveloping zone composed of compacta, the processes of gestation in the tube are the same as those in the uterus, modified only, as we would naturally expect, by the absence of the decidua and the thinness of the tube wall."

Part III takes up the relation of the chorionic epithelium to chorio-epithelioma. A description is given of a uterine growth of exceedingly malignant character occurring after abortion and labor, or even after tubal abortion, the clinical symptom being uterine hemorrhage even after repeated curettings, very early metastases, especially in the lungs and vagina, and early death, through hemorrhage, cachexia or septic infection. In other words, deciduoma malignum is described from a developmental point of view but called by the writer chorio-epithelioma as a more appropriate name.

The book is well got up and is a credit to the publishers.

Tumors: Innocent and Malignant, Their Clinical Characters and Appropriate Treatment. By J. BLAND-SUTTON, Surgeon to the Chelsea Hospital for Women, Assistant Surgeon to the Middlesex Hospital, London. Third edition. Chicago: W. T. Keener & Co. 1903.

This is the third edition of this book. We are convinced that it is the best book of its size on the clinical character and treatment of tumors, innocent and malignant. The writer has presented a classification of tumors, but he is sufficiently discreet to recognize that at the present moment no classification will stand destructive criticism. The peculiar value of the book is that one may turn to it, as we have done during the past few months, for information. In using the book in this way we have never been disappointed. The book can in no sense of the word be termed a histological consideration of tumors, but it gives the gross appearance of tumors. It is a book that every surgeon should have for reference. It is free from dogmatism and empiricism. This is in a large degree due to the fact that the writer is familiar with the various tumors that occur in plant life and in the lower animals. The book is well but not profusely illustrated. The publishers are to be congratulated on the make-up of the book.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JANUARY 14, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 and 29 Bromfield Street, Boston, Mass.

FINAL REPORT OF THE ROYAL COMMISSION UPON ARSENICAL POISONING.

Allusion has already been made in the Journal [1] to the first report of this Commission, which was appointed in February, 1901, after the serious outbreak of arsenical poisoning among beer-drinkers in Manchester, England, in the previous year. The same commission has now made its final report (Nov. 14, 1903), after holding numerous hearings and examining twenty-nine witnesses. This report embraces the following topics:

(1) Further observations regarding the epidemic of arsenical poisoning in 1900, and as to the medical and public health aspects of the evidence received regarding arsenic in beer and food.

(2) The suggested relation between the disease "beri-beri" and arsenical poisoning.

(3) Tests for arsenic in foods and substances used in the preparation or manufacture of food.

(4) Ways in which foods are liable to become contaminated by arsenic.

(5) Precautions which should be taken by manufacturers to exclude arsenic from foods.

(6) Present means of official control over purity of food, in relation to arsenic.

(7) Recommendations as to improvements in official control over the purity of food.

(8) Recommendations as to the proportions of arsenic in food which should now be held to constitute an offence under the Food and Drug Act.

[1] Final Report of the Royal Commission Appointed to Inquire into Arsenical Poisoning from the Consumption of Beer and other Articles of Food or Drink. Part I. Final Report. London, 1903.

In the first place the following points are illustrated by this investigation: That due precautions were taken to prevent further sale of the Bostock sugar which has plainly caused the poisoning; that the whole number of persons who suffered from arsenical poisoning in this epidemic "was certainly 6,000, and probably the number was in fact very considerably greater." A total of 70 fatal cases occurred, and "it is evident, however, that deaths thus certified do not represent the whole number of cases in which death resulted." The medical officer of health, of Manchester, also notes a remarkable decrease in the birth-rate during the period embraced in the epidemic of poisoning.

The symptoms detailed were chiefly "inflammation of mucous surfaces, with coryza, huskiness, lachrymation, gastro-intestinal disturbance and diarrhea; peripheral neuritis affecting sensory and motor nerves, and in some cases associated with herpes or with well-marked erythromelalgia, and recent pigmentation corresponding to that which not infrequently occurs in persons taking arsenic for long periods."

There is evidence to show that such cases had occurred in other parts of England and in earlier years without recognition. Cases of so-called 'alcoholic neuritis" and "alcoholic heart" have notably diminished since precautions have been taken to free the supply of beer from arsenic.

Observations are also presented upon the elimination of arsenic by the various organs, and especially by the hair. Observations upon patients taking arsenic in regular doses, and upon control cases in which none was taken, showed a notable increase in the former. In 38 out of 41 control cases the hair was free from arsenic, and in the remaining 3 it was present only in very minute quantities.

In closing this portion of the report the Commission concludes "that it would be unwise to express an opinion that any quantity of arsenic, however small, is to be regarded as admissible in any articles of food, and we think is should be the aim of the food manufacturer to exclude arsenic altogether from his products."

With reference to the possible causative connection of arsenic with the disease known as "beri-beri" the Commission considers the evidence as inconclusive.

With reference to the subject of tests for arsenic in food, preference appears to be given to the Marsh-Berzelius test, since "Where various substances are taken in quantities which have been found practically convenient, the

presence of arsenic will be detected, when in amounts well below 1-1000th grain per pound, or (in the case of liquids) well below 1-300th grain per gallon."

The electrolytic method has been adopted at the government laboratory. With reference to the Reinsch test, the Commission concludes that for the purposes of food analysis " it must be considered unnecessary and may even be misleading."

Of the ways in which food is liable to become contaminated with arsenic, the Commission enumerates first the substances used in the preparation of food, which are liable to contain arsenic. These are sulphuric acid, largely employed in the manufacture of glucose, invert sugar, glycerine, mineral and coal-tar colors and caramels, phosphoric acid and its compounds (in mineral waters, baking-powders, etc.), boric and a few other chemicals; malt and hops (from the fuel used in drying), beer, syrup and treacle, vinegar, Demerara sugar and a few other articles of minor importance. Experiments were also made with crops grown on arsenical soil, and the amounts found in such crops was inappreciable. As to precautions to be taken by manufacturers to exclude arsenic from food preparations the Commission discusses the question of guarantees of purity, and concludes that the manufacturer can guard against arsenical contamination (1) " by obtaining adequate assurance from the vendor that the ingredients which he purchases are satisfactory in respect to arsenic (having regard to the limits which the evidence before the Commission shows to be already practicable) and by taking care that their intended use for food purposes is known to the vendor. (2) By testing any ingredients which he purchases, or himself prepares."

The means of official control over the purity of food, in relation to arsenic, are carried out under the laws relating to the Sale of Food and Drugs, the Public Health Acts and the Revenue Acts. By means of different officials these laws are available (*a*) to prevent ingredients of food which are contaminated by arsenic from being used by the food manufacturers; (*b*) to prevent finished food products contaminated by arsenic from being sold to the public.

The Commission recommends that the Local Government Board be given greater power to secure the purity of the food supply, and that a specially trained expert be provided who shall exercise constant supervision in this direction. The necessity of official standards of purity is also urged. It is also recommended that in prosecution of retailers, the manufacturer or wholesaler may also be brought into the same case, if shown to be responsible. Medical officers of health should also be authorized to " lay an embargo on the sale of suspected articles " pending their examination or analysis.

Finally, the Commission proposes a limit of arsenic in articles of food as follows: " In our view it would be entirely proper that penalties should be imposed under the Sale of Food and Drug Acts upon any vendor of beer, or any other liquid food, or of any liquid entering into the composition of food, if that liquid is shown by an adequate test to contain 1-100th of a grain or more of arsenic in the gallon; and with regard to solid food — no matter whether it is habitually consumed in large or small quantities, or whether it is taken by itself (like golden syrup) or mixed with water or other substances (like chicory or carnos) — if the substance is shown by an adequate test to contain 1-100th grain of arsenic or more in the pound."

A MEETING IN BALTIMORE TO DISCUSS THE TUBERCULOSIS CONGRESS SITUATION.

ON Jan. 28, 1904, at 8.15 P.M., there will be held in Baltimore, at McCoy Hall of the Johns Hopkins University, under the auspices of the Maryland Tuberculosis Commission, an informal meeting of American physicians and hygienists interested in the tuberculosis problem of this country. The object of the meeting will be to form a national committee to represent the American medical profession at the International Congress on Tuberculosis, to be held in Paris in 1905. There will also be a free discussion of the announced Congress on Tuberculosis in St. Louis under the leadership of Mr. Clark Bell, and the other tuberculosis congress to be held in Washington in 1905 under the leadership of Dr. Daniel Lewis, or as it is now called," The American Antituberculosis League." It is to be hoped that the deliberations at this meeting will result in an understanding between all parties concerned, and that all individualism and partisanship will be supplanted by true love to humanity, by genuine scientific and practical methods, and by the highest professional motives. If it is the unanimous opinion of the medical profession that there should be an American Congress on Tuberculosis previous to the one which is to meet in Paris next year, it should

be thoroughly representative and an honor to the American medical profession.

Prof. Wm. H. Welch, of Johns Hopkins, has kindly consented to preside. All communications relating to this meeting should be addressed to the Secretary *pro tem.*, Dr. H. Barton Jacobs, 11 Mount Vernon Place, Baltimore, Md.

Those of our readers who are not yet familiar with the present tuberculosis congress situation in America, we beg leave to refer to an open letter by Dr. S. A. Knopf of New York, entitled, "American and International Tuberculosis Congresses and Tuberculosis Exhibits for the years 1904 and 1905," which appeared in the BOSTON MEDICAL AND SURGICAL JOURNAL of Dec. 5 last, and to our editorial comments on the subject of the same date.

HEALTH COMMISSIONER OF NEW YORK.

NEW YORK appears to be open to congratulations on the appointment of Dr. Thomas Darlinton as Commissioner of Health. Although medical men have always been concerned in dealing with the sanitary affairs of the city, they have never been conspicuous as members of the health department. Recently, as we have previously stated, the medical profession was debarred from holding the highest office in the board of health. This fortunately is no longer true, and now, with the appointment of Dr. Darlington, there seems to be no reason why the work of the board of health may not be controlled, as it should be, by competent members of the medical profession. The *New York Medical Journal* speaks in the following terms of this appointment:

> Dr. Darlington has been long enough in medical life to have imbibed an ample experience in matters touching closely upon the fundamental work of sanitary authorities, and circumstances have given him unusual experience in such matters, notably the management of tuberculous disease and the sanitation of school children. On the other hand, he is not so old as to have become imbued with theories difficult for an old man to discard as exploded or to hold on probation. He is in the prime of life, at the height of his powers. Above all else, Dr. Darlington has been a practising physician in the city for years, one who has met with the reward of material success and the esteem of the community. We feel sure that his professional brethren will support and assist him in his official work to the extent of his just expectations, and we look to his administration to reflect credit upon our profession.

THE BOSTON ASSOCIATION FOR THE RELIEF AND CONTROL OF TUBERCULOSIS.

THIS Association met on Wednesday evening, Jan. 6, at the rooms of the Twentieth Century Club, to listen to an address by Dr. S. A. Knopf of New York City, upon "Our Duties in the Combat of Tuberculosis." He first described the character of the disease, contrasting the degree of its communicability with that of smallpox. The methods of prevention were fully treated as well as the modes of treatment. In speaking of the necessity for the destruction of the sputum of consumptives, he detailed his own amusing experiences in the street cars of New York City.

He was especially severe in his denunciation of the many forms of quackery and of consumption cures which exist in every large city, as well as of the numerous patent medicines advertised for the same purpose, which are not only delusive frauds, but impoverish the poor by enticing them to spend their little savings for things which are worse than useless, when the same amount expended in securing better ventilation and more wholesome food might be productive of good results.

The subject was treated in a very clear and comprehensive manner, and was freely discussed by members of the Association. After the meeting a reception was given to Dr. Knopf.

MEDICAL NOTES.

PROF. BURDON SANDERSON WILL RESIGN. — Sir John Burdon Sanderson will shortly resign the position of Regius Professor of Medicine at Oxford. He succeeded the late Sir Henry Acland in 1895. It has been his intention to resign at the age of seventy-five years, an age which he will reach in a few weeks.

FIRST INTERNATIONAL CONGRESS OF SCHOOL HYGIENE. — The first International Congress of School Hygiene will be held at Nuremberg, Bavaria, from April 4–9 next. A number of important communications from well-known authorities are already announced. Communications should be addressed to Herr Max Versen, Fränkischer Kurier, Nuremberg.

TYPHOID FEVER IN MONTREAL. — It is reported that about a thousand cases of typhoid fever have appeared in Montreal and a half dozen smaller towns in the neighborhood. Fresh cases are being reported in spite of all efforts to check the spread of the disease.

DEATHS AMONG PHYSICIANS. — From statistics compiled by the *Journal of the American Medical Association* it appears that during 1903 the number of deaths of physicians in the United

States and Canada was 1,648, probably within 5% of the total mortality in the medical profession in North America. It is estimated that the number of physicians in this country is about 120,000.

Among those who died the years in practice varied from one to seventy-five. The greatest number of deaths occurred in the twenty-fifth year of practice, in which 51 were recorded. Of the entire number 209 had practiced more than fifty years, and two had been in practice seventy-five years at the time of their deaths.

JOURNAL OF INFECTIOUS DISEASES. — The first number of the previously announced periodical entitled *The Journal of Infectious Diseases* has appeared. This journal is founded by the Chicago Memorial Institution for Infectious Diseases, and, as we have already stated, is under the editorship of Drs. Ludvig Hektoen and Edwin O. Jordan, in conjunction with Dr. Frank Billings, Dr. F. G. Novy, and Prof. W. T. Sedgwick. The aim of this new journal is to occupy the special field of infectious disease, and to include in its publications only such contributions as bear with reasonable directness upon this general topic.

The first number amply fulfils the expectations which have been formed of the journal. It is admirably printed, and in general appearance is not unlike the *Journal of Medical Research*, after which it appears to be in a measure modeled. A number of papers, embodying original investigation, appear in this issue, among others an important one by Novy and McNeal on the "Cultivation of Trypanosoma Brucei."

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Jan. 6, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 48, scarlatina 40, typhoid fever 8, measles 172, smallpox 0.

DEMONSTRATION OF PATIENTS TREATED BY LORENZ METHOD. — At a special meeting of the Boston Society for Medical Improvement, held Jan. 7 at the Children's Hospital, patients who were treated by Dr. Lorenz in December, 1902, were demonstrated to the members of the Society. In addition to these the results of various methods of treatment for congenital hip dislocation extending over a period of twenty years, as practised at the Children's Hospital, were given, together with a demonstration of a new apparatus devised by Mr. Bartlett.

CENTENARIANS. — Mrs. Harriet B. Litthale of Tyngsboro, Mass., died Jan. 7, at the reputed age of one hundred and three years. Before her death her family was represented by five generations.

Elijah J. Woodruff died in Toledo, Ohio, recently at the age of one hundred and one years. He was born in Watertown, Conn.

NEW YORK.

WORK OF BOARD OF REGENTS. — A summary of the work of the Board of Regents of the University of the State of New York reported from Albany shows that during the year 1903 the Regents licensed, as a result of state examinations, 633 physicians, 176 dentists and 17 veterinary surgeons, and that, in addition, they licensed under exemptions in the laws regarding the professions 69 physicians, 36 dentists and 6 veterinary surgeons.

MORTALITY IN DECEMBER. — The weekly reports of the Health Department show that during the month of December the mortality in the city represented an annual death-rate of 18.53, as against 17.27 in November and 17.52 in December, 1902. The corrected death-rate, excluding non-residents and infants under one week old, was 17.69. Among the diseases in which there was an increased fatality are the following: The weekly average of deaths from diphtheria and croup increased from 40 in November to 47.25 in December; from scarlet fever, from 7.75 to 17.75; from influenza, from 5.5 to 8; from pneumonia, from 139 to 186.75; from broncho-pneumonia, from 69 to 88.25; from acute bronchitis, from 35 to 37.5; from pulmonary tuberculosis, from 146.5 to 162; from cancer, from 44.75 to 52.75. Among the few diseases in which there was a diminished mortality were the following: The weekly average of deaths from typhoid fever declined from 17.25 to 13; from diarrheal diseases, from 42.5 to 34.5; from diarrhea in children under two years, from 35.5 to 25.

DEATHS FROM CAISSON DISEASE. — During the past week there have been two deaths from caisson disease among the men employed in the construction of the new Manhattan bridge, the third of the great bridges over the East river connecting the boroughs of Manhattan and Brooklyn. Altogether there have been five victims of the disease in the work on Manhattan bridge. The last one, Martin Dolan, was an inspector of masonry work. His death occurred on the first day of his employment in that capa-

city, and he had spent less than half an hour in the caisson when it took place. The bottom of the caisson is 92 feet under the river, and the pressure there is 45 pounds to the square inch. Like the two compartments above, this lower one is provided with an airlock. Dolan, it is stated, had passed the physical examination of his own physician, as well as of the civil service physician, and had been pronounced fit. As a result of his death the bridge commissioners immediately had a conference with Health Commissioner Darlington for the purpose of seeing what steps could be taken to make the work more safe. The first thing done was to instruct Dr. William E. Weber, of the Board of Health, to make a careful examination of all the engineers and laborers employed in caisson work, noting their present condition and each man's experience, and from his report it is expected that the health department will gain additional information of value in regard to the characteristics of the disease and as to the class of men who can be employed in the work with the least risk.

Radium in Therapeutics. — In a lecture on Radium in Therapeutics, delivered Jan. 5, before the William Pierson Medical Library Association of Orange, N. J., Dr. Robert Abbe of New York expressed the opinion that this agent does not act as quickly and satisfactorily as the Roentgen ray. Experiments made by others and himself indicated, he said, that radium is of especial value in removing birthmarks. Most of the reports in the press in regard to the wonderful cures effected by it were exaggerated. Especially was this true as regards cases of blindness; but, at the same time, it was of great service in demonstrating to the surgeon whether or not the optic nerve is destroyed or whether an opacity of the pupil exists.

Care of Water Supplies. — In his annual message, submitted to the Legislature Jan. 6, Governor Odell makes the following statements in regard to the care of the water supplies: "The report of the State Commissioners of Health shows that nearly 25,000 cases of typhoid fever, with a mortality of 1,635 cases, occurred in the state during 1903. Similar epidemics have occurred in other states. Inasmuch as typhoid fever is very frequently caused by polluted supplies of potable water, it is now classed as a preventable disease. The general acceptance of this view resulted in the passage of Chapter 468 of the Laws of 1903, entitled 'An act to amend the public health law relative to the discharge of sewage and other waste matter into the waters of the state.' The proper enforcement of this law is vested in the State Department of Health, and upon its wise and judicious enforcement will depend the lives and health of the people in a large degree. A complete record of the sources of public water supplies, and the possible conditions which may produce epidemics of typhoid fever or other infectious diseases, should be secured by the Health Commissioner, and I recommend that an appropriation be granted by the Legislature for this purpose."

Bequests. — By the will of the late Hon. James J. Belden of Syracuse, N. Y., the following bequests are left: Syracuse University, $100,000; Syracuse College of Medicine, Syracuse Home, Women's and Children's Hospital, St. Joseph's Hospital, $50,000 each; Hospital of the Good Shepherd, $10,000; three orphan asylums, $5,000 each.

Verdict of $12,500 for Personal Injury. — A verdict for $12,500 damages against the New York Central and Hudson River Railroad Company, which was secured by Alfred N. Newton in the Supreme Court on Jan. 4, is of interest from the fact that the plaintiff did not have a visible injury which could be demonstrated to the jury, the support of his claim resting entirely on expert medical evidence. Mr. Newton was in the collision in the Park Avenue tunnel which occurred Jan. 8, 1902, and well-known physicians testified that as a result of the shock received by him from the accident he had become affected with heart trouble. The evidence of witnesses called by the defence to the effect that the plaintiff had a weakened heart prior to the accident and that the company was not therefore responsible proved unavailing in convincing the jury that such was the fact.

Constitutionality of Tenement House Act. — On Jan. 8 the Appellate Division of the New York Supreme Court handed down a decision in which the constitutionality of the Tenement House Act, which asserts the right of the Tenement House Commissioner to compel the making of alterations required to insure proper sanitary conditions, is upheld. The case was appealed to this court by the Tenement House Departments of New York City to compel Kate Moeschen to install sanitary plumbing in premises owned by her, as specified in the act. The defendant claimed that the law imposed an unreasonable exaction, and was therefore in violation of the State Constitution.

Obituary.

JOSIAH LITTLE HALE, M.D.

DR. HALE died in Brookline, of heart disease, Dec. 21, 1903. He was born in Geneva, N. Y., April 1, 1841, and graduated from Hobart College, of which his father was president, in 1860, having been obliged to interrupt his college course for a short time because of illness. For two years he was in the employ of the Atlantic Insurance Company of New York. In 1865 he took up the study of medicine at the Harvard Medical School, from which he graduated in 1868.

In 1867 he was appointed house pupil at the Massachusetts General Hospital; his colleagues were Drs. H. J. Pratt, H. H. Hastings, H. H. A. Beach, Rufus P. Lincoln and Thomas W. Waterman. After leaving the hospital he went to Vienna for two years to pursue his medical studies, returning to Boston in 1870. He was appointed district physician of the Boston Dispensary in 1872, retaining his position for a year. In the same year he was appointed physician at the central building and remained on the staff for ten years.

He practised in Boston until 1882, when he was obliged to retire from active work on account of ill health, and went to Brookline, where he remained up to the time of his death. He published "Reports of Surgical Operations at the Massachusetts General Hospital" in Vol. 78, 1868, of the BOSTON MEDICAL AND SURGICAL JOURNAL. He was a member of the Massachusetts Medical Society up to the time of his death, also of the old Observation Society and of the Natural History Society.

Dr. Hale was an enthusiast in his profession and did not relinquish its practice until forced to do so by persistent ill health. For a long time he made a brave fight in his efforts to continue his work, but it was finally of no use; he had to give up everything that required continuous exertion. For a prolonged period he was subject to severe congestive headaches complicated with insomnia and a few years before his death heart disease developed. He found that at times by going on the water his headaches were relieved; he could sleep better, and hence he was obliged to take frequent short journeys. But the relief was only temporary, the old symptoms always returning with renewed intensity.

He was well fitted for a successful practitioner, not only being full of enthusiasm but of sympathetic and kindly manners and genial disposition. Further, he was a careful and accurate observer, taking great interest in minute experimental investigations.

For many years he was a student of genealogy and had made extensive researches into the history of his ancestors, some of whom fought in the Revolution. He was a member of the Society of Colonial Wars and of the Sons of the American Revolution.

Dr. Hale possessed a fund of information on many subjects which he was always delighted to impart to those interested. If he had been well enough to apply his mind to investigations in one direction, there is little doubt that he might have achieved valuable and important results.

His interest in everything that was going on about him; his geniality and amiability of disposition, and his strong character enabled him for many years to bear exhausting disease with patience and fortitude. Those who met him from day to day, and saw how cheerful and hopeful he was, could form no idea of the burden he was carrying. But when his friends now look back on his life and in the light of a more intimate knowledge realize what he passed through, they are impressed with the fact that his trials and deprivations were greater than those that fall to the lot of ordinary men. Bearing them in the noble and uncomplaining way that he did, he was, in the highest sense of the word a true hero, and his example should not pass unnoticed or be forgotten. W. C.

Miscellany.

AMERICAN SOCIETY OF TROPICAL MEDICINE.

THE first public meeting of the American Society of Tropical Medicine was held at Houston Hall, of the University of Pennsylvania, Philadelphia, on January 9, 1904, Dr. James M. Anders, a vice-president of the society, in the chair. A brief statement of the scope and workings of the society was made by the secretary, Dr. Joseph McFarland, after which the speaker of the evening, Dr. James Carroll of the United States Army, and a former member of the commission appointed by the Surgeon-General of the United States to investigate yellow fever at Havana, Cuba, made an address upon "The Etiology of Yellow Fever."

Dr. Carroll reviewed in an interesting manner the early researches upon the etiology of the disease, giving special consideration to the work of Freire, Sanarelli and Finlay, then reviewed the work of the commission whose researches have now become world-wide, and resulted in the proof that we have no reason to believe that yellow fever is propagated by any other means than the bites of the mosquito known as *Stegomyia fasciata*. It is only the female mosquito that bites, therefore only the female mosquito that becomes infected. The mosquito is able to impart the disease only after twelve days have elapsed since its own infection, and may retain the ability to infect after many months, providing it does not meet with destruction in the meantime. A description of the experiments made to show the infectiousness of *fomites* seemed to exclude all possibility of yellow fever being transmitted directly.

It was with pleasure that the speaker reported that the confirmation of all of the work of the United States commission had been given by the more recently appointed French commission.

Information regarding the society, its objects and its workings, can be had by applying to the secretary, Dr. Joseph McFarland, Medico-Chirurgical College, Philadelphia.

ARGON IN ATMOSPHERIC AIR.

AN interesting communication was made recently to the Paris Academy of Science on the above subject. M. Moissan reported that he had followed up the researches of M. Schloesing who had already determined the proportion of argon existing in certain specimens of air. By utilizing the property which calcium possesses of absorbing at one and the same time the oxygen, the nitrogen and all the impurities which are found in atmospheric air, and by the use of a special apparatus of which he had already given a description to the Academy, M. Moissan had been able to estimate the amount of argon found in the air of Paris, of London, of Berlin, of Vienna, of St. Petersburg and of Athens. In all these towns the amount was identical. The same proportion of argon was also found in samples of air taken in the Channel, in the Ionian Sea in the Gulf of Naples, in the valley of Chamounix, at the Grande Mulets and at the top of Mont Blanc. Air collected in the middle of the Atlantic appeared to be slightly richer in argon than that from other places. Calcium will combine with the hydrogen which is produced during reactions, forming a hydrate which is not decomposed at a temperature of 500° C. All this illustrates the remarkable uniformity of the composition of the air. M. Moissan does not appear to refer to the question of small quantities of helion which may possibly occur in the air or as to what its behavior would be when exposed to hot calcium. The results as regards argon are of interest and the observation that the air collected in the middle of the Atlantic appeared to contain a slightly greater proportion of argon than that from other places is probably in some way connected with its solubility in water and the great and frequent variations of atmospheric pressure to which the Atlantic ocean is liable. — *Lancet.*

Correspondence.

MEDICAL REGISTER FOR NEW ENGLAND.

BOSTON, JANUARY 8, 1904.

Mr. Editor: May I ask you to state that I have not had and do not now have any intention of republishing the *Medical Register for New England*, inasmuch as I find that the members of the profession are not disposed to give it support; that I have not sold nor do I propose to sell my copyright; and that any statements to that effect, by whomsoever made, are entirely without my authority and are evidently fraudulent.

Very truly yours,

FRANCIS H. BROWN, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JAN. 2, 1904.

Deaths reported, 3,730; under five years of age, 921; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 770, acute lung diseases 772, consumption 393, scarlet fever 38, whooping cough 12, cerebrospinal meningitis 7, smallpox 16, erysipelas 11, puerperal fever 16, measles 28, typhoid fever 61, diarrheal diseases 66, diphtheria and croup 116.

From whooping cough, New York 2, Chicago, 1, Philadelphia 1, Baltimore 2, Pittsburg 3, Holyoke, Chicopee and Woburn 1 each. From smallpox, New York 1, Philadelphia 11, Pittsburg 4. From cerebrospinal meningitis, New York 3, Baltimore, Boston, New Bedford and Brockton 1 each. From erysipelas, New York 4, Chicago 3, Pittsburg 1, Boston 2, Cambridge 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Dec. 19, the death-rate was 17.8. Deaths reported, 5,159; acute diseases of the respiratory organs (London) 186, whooping cough 113, diphtheria 43, measles 134, smallpox 3, scarlet fever 24.

The death-rate ranged from 8.2 in Kings Norton to 36.0 in Preston; London 16.8, West Ham 15.9, Brighton 17.0, Southampton 18.5, Plymouth 17.7, Bristol 16.9, Birmingham 19.7, Leicester 19.4, Nottingham 18.0, Liverpool 22.0, Bolton 16.8, Manchester 19.3, Salford 20.7, Bradford 20.1, Leeds 19.2, Hull 14.2, Cardiff 17.2, Rhondda 22.7, Grimsby 10.3, Merthyr Tydfil 21.1.

METEOROLOGICAL RECORD.

For the week ending Jan. 2, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JAN. 7, 1904.

IRWIN, FAIRFAX, surgeon. Detailed as member of Revenue Cutter Service Retiring Board to be convened at Philadelphia, Pa. Jan. 5, 1904.

ROSENAU, M. J., passed assistant surgeon. Four days' leave of absence from Jan. 1, 1904, under paragraph 189 of the regulations.

KORN, W. A., assistant surgeon, Detailed as member of Revenue Cutter Service Retiring Board to be convened at Philadelphia, Pa. Jan. 5. 1904.

AMESSE, J. W., assistant surgeon. Granted leave of absence, on account of sickness, for 7 days. Jan. 4, 1904.

ASHFORD, F. A., assistant surgeon. Relieved from duty at Chicago, Ill., and directed to proceed to Milwaukee, Wis., and assume temporary command of the service at that port. Jan. 4, 1904.

BROCK, G. H., pharmacist. Granted leave of absence for one day. Jan. 5, 1904.

MAGUIRE, E. S., pharmacist. Granted leave of absence for seven days from January 1. Jan. 5, 1904.

BOARDS CONVENED.

Board convened to meet at the marine hospital, Chelsea, Mass., January 11, 1904, for the physical examination of an officer of the Revenue Cutter Service. Detail for the board: Surgeon R. M. Woodward, chairman; assistant-surgeon W. C. Rucker, recorder.

Board convened to meet at Washington, D. C., for the purpose of considering revision of medical books on contract, and preparation of list of professional books, etc. Detail for the Board: Assistant surgeon-general L. L. Williams, chairman; assistant surgeon-general H. D. Geddings; assistant surgeon A. J. McLaughlin, recorder.

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING JAN. 9, 1904.

H. G. BEYER, surgeon. Upon completion of board duty in connection with barracks ordered to Boston, Mass., for special temporary duty and thence to the Naval Museum of Hygiene and Medical School, Washington, D. C.

A. E. PECK, assistant surgeon. Ordered to the "Pensacola."

M. K. ELMER, assistant surgeon. Detached from the "Pensacola" and ordered to the "Hancock."

SOCIETY NOTICE.

THE PHILADELPHIA NEUROLOGICAL SOCIETY. HALL OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA. — A stated meeting of the Philadelphia Neurological Society will be held on Tuesday, January 26th, 1904, at 8.15 p. m. In celebration of the twentieth anniversary of the organization of the Society the following special program has been arranged. Papers will be read as follows: Dr. James Hendrie Lloyd, "The Metaphysical Conception of Insanity;" Dr. S. Weir Mitchell, "The Mental Processes by which the Rest-Treatment was Developed;" Dr. J. Chalmers DaCosta, "The Surgical Operations Applicable in Insanity;" Dr. Francis X. Dercum, "Mystic Medicine." A cordial invitation is extended to all members of the medical profession to attend the meeting.

AUGUSTUS A. ESHNER, Secretary.
224 South Sixteenth Street.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — The annual meeting of the society will be held in Sprague Hall, Medical Library Building, on Monday, January 18th, 1904, at 8.15 p. m. Papers: Dr. Henry Jackson, "Tubercular Meningitis in Adults;" Dr. Francis Williams, "A Comparison between the Medical Uses of the X-rays and the Salts of Radium."

ARTHUR K. STONE, M. D., Secretary.

RECENT DEATHS.

BENJAMIN HALL HARTWELL, M.D., M.M.S.S., died in Ayer, Jan. 6, 1904, aged fifty-nine years, of pneumonia. Dr. Hartwell had been a pension examiner for twenty-eight years; he was coroner from 1871 to 1877 and for many years had been medical examiner of his district. He was graduated from the Jefferson Medical College, of Philadelphia. He had a large practice in his neighborhood and was much respected and trusted.

CORNELIUS E. BILLINGTON, M.D., of New York, died on Jan. 9, aged sixty years. He was graduated from the medical department of the University of the City of New York, in 1863, and served for a time as an army surgeon during the Civil War. Dr. Billington was for many years a district physician for the Demilt Dispensary, and during this period, which was before the days of antitoxin, attracted considerable attention by his successful treatment of diphtheria by means of tincture of ferric chloride combined with potassium chlorate.

JAMES FRANCIS FERGUSON, M.D., of New York, died at Central Valley, N. Y., on Jan. 6. He was born in New York City, Oct. 10, 1839. He was graduated from the medical department of the University of the City of New York in 1861 and from Bellevue Hospital Medical College in 1862. He served with distinction as a surgeon during the Civil War, and shortly before its close was breveted Lieutenant-Colonel of New York Volunteers. His professional appointments in New York are as follows: attending surgeon Bellevue Hospital, Outdoor Department, 1870–71; visiting surgeon to the Blackwell's Island Hospital, 1872–92; visiting physician to the Hospital for Nervous Diseases, 1886–92; consulting physician to the Charity (now City) Hospital, since 1892.

STUART H. REED, M.D., of Madison, N. J., died on Jan. 6, from pleuro-pneumonia. He was born in South Carolina, Oct. 10, 1854. He was graduated from Williams College in 1878, and from the College of Physicians and Surgeons, New York, in 1881. Dr Reed was a member of the first Board of Councilmen of Madison, and served for a number of years on the Board of Education. He was also for several years physician for the Board of Health and at the time of his death was a member of the Commission of Appeals.

GEORGE WINSLOW FOSTER, M.D., has recently died in Bangor, Maine, at the age of fifty-nine. After practicing for many years in the West, he returned East to the Government Hospital for the Insane in Washington, in 1893, where he remained until he took the position of superintendent of the Eastern Maine Insane Hospital at Bangor, an institution opened under his direction in 1901. Dr. Foster was graduated at Bowdoin College and at the Maine Medical School, and was a member of various medical societies.

Lecture.

CLINICAL LECTURE ON EPITHELIOMA AT MASSACHUSETTS GENERAL HOSPITAL.

BY J. COLLINS WARREN, M.D., BOSTON,

Professor of Surgery, Harvard Medical School.

GENTLEMEN: It is my desire to say something to you to-day in regard to cancers on the surface of the body, or the so-called epithelioma. I take up the subject with you at this time because I consider it a particularly favorable moment.

As you are aware, a great change has taken place in our attitude toward, and our treatment of, this form of malignant disease, since the introduction of the x-ray, and I think the surgeon is all the more interested as he finds that some of his patients having this disease are disappearing and going to the dermatologists and the x-ray specialists. In this hospital I find that rodent ulcers are now treated largely in the skin clinic, and we see comparatively few of such cases in the surgical wards, and I might say that this is true also in private practice.

Some thirty years ago I wrote an article on this subject and as a result of that investigation I have seen many cases of rodent ulcer, and have become familiar with the treatment used at that time and since. In the early days the treatment was with caustics to a great extent, curetting and burning with nitrate of silver, and burning with the actual cautery; but as time went on and asepsis was perfected, I began to use the knife, with the result that the cures were more rapid and much more complete than they were by the old methods of cauterization. Of course there were cases which were beyond the reach of the knife and very difficult to treat, and others so situated that removal by the knife produced great disfigurement. You will see presently to what extent the x-ray has been helpful in treating these ulcers. Occasionally I have met with cases which have proved fatal in spite of all treatment, and cases which have produced the most disfiguring ulcerations. In my "Surgical Pathology" you will see the picture of a man with one side of his face destroyed by an ulcer, and in the "International Text-Book of Surgery" you will find the portrait of a man the whole side of whose face, half the nose, the eye, cheek and the side of the mouth are gone, as a result of disease of long standing. Manifestly, such cases are beyond all therapeutic aid, and succumb in spite of any kind of treatment. Whether with the advent of the x-ray such cases will become rarer is a point which will be watched with a great deal of interest.

Considering now the pathology of epithelioma, I wish to impress upon your minds that there are two principal varieties. One which is almost a benign growth, and another which approaches more nearly to cancer in a clinical sense. It has long been recognized that carcinoma in this region of the body is very much less malignant than carcinoma of the breast and intestinal canal, for example, and in the early days when little was known about the general characteristics of cancer, these growths of the skin, being found to be composed of large pavement-like cells, were known as epitheliomata; hence, it was believed that epithelioma was a different kind of disease from that which was then recognized as cancer. Of course, until we are able to state more definitely the true nature of cancer, it is useless to try to classify its varieties to any great extent. We are sufficiently familiar with the pathological anatomy of the disease, however, to know that all these cases should be recognized as cancer, although they may be greatly modified in the appearance of their histological structure by different regions of the body in which they grow.

Now in cancers of the skin we must recognize two varieties. First a very superficial type, known as the rodent ulcer, a small-celled epithelial cancer, and second a polymorphous-celled type characterized by larger cells among which the characteristic nests of cells occur. The type of the former of these two varieties is the rodent ulcer of the face, while types of the latter form are cancers of the lip, of the back of the hand, and of the penis.

I shall speak chiefly of the former of these two varieties, cancer of the face, or rodent ulcer, or superficial epithelioma. As you know, the skin is composed of several layers. Superficially we have the epithelial cells and a horny layer, while underneath are the cutis vera and the subcutaneous tissue. Between these, in the rete mucosum, is a layer of small epithelial cells which cover the papillæ and fill the spaces between them. As we approach the surface the cells become distinctly larger, and finally, on the top the cells are dried, have lost their nuclei, and have become scales. The epithelial cell growth found in rodent ulcer corresponds to the small cell type of the rete mucosum. The clinical changes in the rodent ulcer type are very characteristic. An elderly person finds a roughness of the surface on some part of the face with the tendency at some point to the formation of a scab, and there seems to be a weather-beaten condition of the complexion. There is a growth and thickening of the upper layers of skin known as keratosis senilis. Eventually the dry scab is picked off, and an ulcer is found. This dries up and seems almost to disappear, but the scab again appears and the patient picks it off, and finally the patient finds that it is always there. And so it may go on for years, the patient accepting it as a mole, and it slowly increases in size, until some day it seems to grow more rapidly. As with all malignant growths, it has an early stage when the growth is very slow; then suddenly it takes on more rapid growth; the patient becomes alarmed finally, and seeks relief. Microscopic examination of the affected part at this time shows an undergrowth of cells gradually working down into the skin in more or less finger-like processes. Thus we have an infiltration

into the tissues below and this keeps on until the center breaks down and an ulcer is thus formed. If a bit of the ulcer is cut out and examined microscopically, we find the papillæ becoming somewhat enlarged at that point, and the cells between them gradually pushing down into the interior, and little patches of similar cells here and there between them. We find them composed of cells similar to the cells of the rete mucosum as a rule without the cell nests. One of the great clinical features of this type is its tendency to remain localized, to remain in the skin itself. It may continue to grow and involve the whole side of the patient's face, but still it remains local — in the skin. It is, however, slowly progressive, and finally attacks bone, nerve, eye and other complicated parts.

Inquiring into the history of such a case the diseased process is found sometimes to have gone on for forty years or more, during which period the growth had been at times imperceptible, but it was always there. On examination you will find no enlargement of the lymphatic glands, and that is a very characteristic feature of the disease which makes the prognosis encouraging, and I want to impress upon you this clinical trait in reference to the after-treatment.

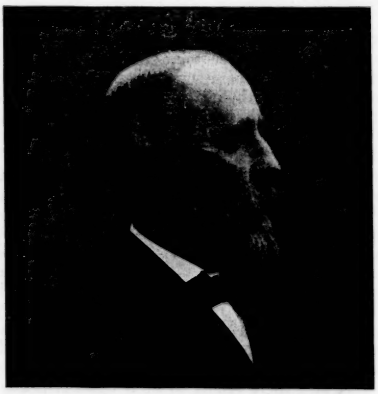

FIG. I.

The second variety is the more malignant type, the typical epithelioma, such as cancer of the lip. We find the papillæ near the vermilion border somewhat enlarged and running down in an irregular way into the tissue below. If we look at one of these prolongations we find onion-like clusters of large cells in the center, while around the edge are rows of more or less columnar shaped cells while the mass of cells in the intervening space is of the most varied character. If we examine the neck of a patient who has a well-developed cancer on the lower lip we shall find, in all probability, enlarged glands under the jaw on the side nearest to the growth, and if the cancer is on the penis the glands of the groins are enlarged, and if on the hands the glands of the bend of the elbow or of the axilia are involved, and as a consequence of this we have a fatal termination in a very much larger percentage of cases than in rodent ulcer, where the growth occurs very slowly, and death only follows as a result of long-continued growth, and invasion of important structures. Here is a photograph (Fig. I) of a man who gradually succumbed in that way, the disease beginning in the tip of the ear and slowly destroying everything in its way until the meninges of the brain were involved and he died with symptoms of cerebral complications. The photograph shows the temporary relief afforded by a plastic operation. A large ulcer occupied the site of the right ear. The patient had been subjected to a prolonged application of caustic at a " cancer cure."

Now I have a series of cases of rodent ulcer which I will show you, gentlemen, without any extended critical remarks as to treatment, then after that I will say something about the operative treatment, as contrasted with the X-ray treatment of the disease.

CASE I. Here is a man fifty-eight years of age who has had this ulceration on the nose for seven or eight years. It began on the side of the nose, then it gradually spread until it covered the whole nose. This is a good example of a very diffuse type. In some cases the disease seems to skim along the surface instead of cutting down deep into it. To what extent has it been helped by the x-ray? It has had fifteen months' treatment. He had two treatments a week at first and is now having one, and there has been a gradual improvement, but there is still well-marked ulceration at certain points. You see the neighboring skin is a good deal reddened. That is not usual. It is simply that in some of the more superficial types we see a secondary inflammation of the skin, The redness may be in part due to the action of the x-rays.

CASE II. This woman is fifty years of age. She has had a growth on the temple for fifteen years. She began treatment in February, 1903, with the x-ray. Since then the growth has diminished in size but it involves the bone near the orbit. She is under treatment now in the skin department. A cancerous growth which is small in size but which has begun to attack deep-seated tissues would seem to me to need the most radical surgical treatment without waiting for the results of x-ray therapy.

CASE III. Man of seventy-eight years. He has a large but very superficial ulcer on the right cheek beneath the eye and extending over the right half of the nose. Twenty years ago he noticed a pimple on the face after an attack of erysipelas. For fifteen years it increased in size. Came to the out-patient department for x-ray treatment, and it has relieved the pain, but not the condition. Examination under the jaws shows no involvement of the glands. This is a small-celled epithelial cancer. You see that it would be necessary to excise nearly the whole cheek, and so it seems reasonable to try the x-ray in a case of this kind. In the diffuse forms this treatment seems particularly well indicated.

CASE IV. This patient has an ulcer the size of a half dollar on the back of the neck. Eight years ago he noticed a pimple on the neck. He scratched it and thinks he poisoned it. He was treated with local applications and at one time the ulcer was excised but the wound did not heal. For one year has had x-ray treatment here. It is growing somewhat smaller, and there is less induration than a year ago. You see he is a rugged man. This seems a favorable case for cure by free excision giving the growth a wide margin and closure of the wound by a plastic operation. (This has since been done.)

Case V. Man of seventy-two years. First noticed a scab about eleven years ago over the scar of an old bayonet wound of right cheek received in the Civil War. Several years later an ulcer formed which soon began to involve the eye. There are now several ulcers in the neighborhood of the orbit and the right side of nose. Came in here about two years ago and has been taking x-rays since then. Now here is a case which seems suitable for x-ray treatment. Operation would be very difficult: the ulcers could be excised but the wounds could not be closed and Tiersch grafts would not hold with any certainty.

Case VI. This man is forty-three years old. Here the ulcer is on upper lid of right eye, which began as a pimple in the upper lid five years ago. The ulceration now extends from the inner canthus to the outer and from the upper edge of eyebrow to the conjunctiva. The outer half of the conjunctival lid is gone. No bone is exposed and the cornea and ocular conjunctiva, although inflamed, do not appear to be involved. He has also an ulcer over the malar bone which was formerly connected with that of the lid. There is vision to light in the right eye. No involvement of the glands. He has received the x-ray treatment for a year and a half. During this time there was one period of increase in the growth. There is now improvement which has been very marked during the past months.

Case VII. In this case there is a history of a blasting accident forty years ago. A few years ago he noticed a scab on the site of the scar on his cheek and also on his nose since that time. He has been treated with x-rays. The ulcer has entirely healed up on the cheek, leaving a slight scar, and there is practically no disease remaining on his nose.

Case VIII. A man seventy-one years of age. Began to have trouble twenty-three years ago on right upper cheek near the eye. He began to go to the dispensary and was treated by salves for a long time; arsenical paste, etc. When he came into my hands, four or five years ago, the whole side of the face was alternate scars and ulcers. Not a continuous ulceration, but a series of sores healing and breaking out. Finally the lids of his right eye had become thickened masses of epithelial disease. I saw that unless something very radical was done he would succumb to the disease. The eyelids were transformed into an epithelial growth and the disease was pushing into the orbit, and would soon become a very malignant instead of a superficial type of cancer. The operation performed was an excision of the integuments of the right side of the face, including the eyebrow, eyelids, cheek and the right half of the nose and a portion of the right half of the upper lip. The lower border of the incision was on a line with the angle of the mouth. To cover this wound a flap was taken from the temple reaching to the vertex, the pedicle of the flap being just above the right ear. The wound of the scalp thus laid bare was covered with Tiersch grafts. The wounds healed well and there has been as you see no return of the disease now some five years since the operation. (Figs. II and III.)

Case IX. I show you a portrait of a patient fifty years of age who is unable to come to-day from a distant city. (Fig. IV.) He came to me three years ago with an enormous ulcer involving the right temple having destroyed the upper half of the right ear from which it took its origin. It was of many years' duration at that time. The discharge, which was free, was offensive. There was no glandular involvement. Although not able to promise a cure I advised excision with plastic closure of the wound as a palliative measure. This operation was done, the wound made by the removal of the ulcer being covered in by a flap taken from the scalp having its pedicle over the occiput. As the flap was bent into place a fold formed at its lower border which fitted neatly into the remaining portion of the ear. The pericranium exposed by this operation was covered by Tiersch grafts. There was no recurrence for one year, at which time two nodules were to be felt in the parietal bone at the upper margin of the flap. These disappeared under the x-ray treatment, but there have been some recurrences since which the ray treatment partially controls. This case illustrates well the great relief afforded by a palliative operation in advanced cases of cancer of the face. A plastic operation removes the foul ulcer and the subsequent postoperative x-ray treatment postpones recurrence. It is in my opinion better not to wait for a complete cure before performing the plastic operation, but to close the wound at once and obtain the benefit and comfort of healing by first intention.

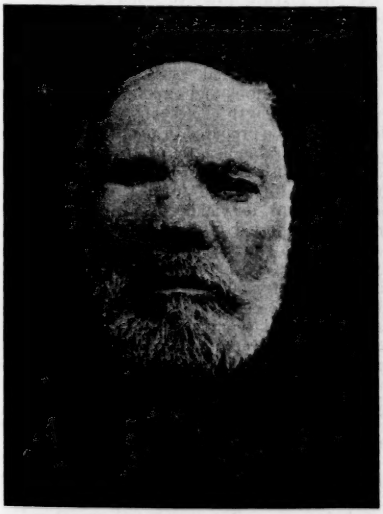

Fig. II.

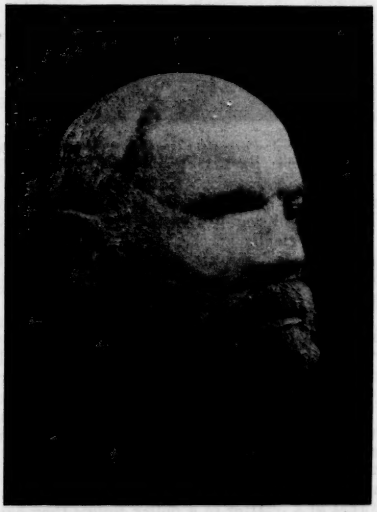

Fig. III.

Excision of right cheek and orbit; wound covered by flap taken from scalp. Tiersch grafting of scalp.

These cases give you examples of the most common aspects of the milder forms of cancer of the skin. They all can be classed in the rodent ulcer group and I have selected them therefore for our study as they are the most favorable types of cancer for the x-ray treatment on account of the superficial character of the growth. An analysis of the cases in the dermatological department of the hospital of which some of these are examples shows favorable results under the x-ray treatment.[1] It is now pretty generally conceded that x-ray therapy has a favorable influence upon very superficial carcinoma but that the more deeply seated growths are not affected by it. We may therefore dismiss at once the more malignant variety of epithelioma so far as this form of treatment is concerned with the statement that it seems hardly justifiable to lose valuable time in treating a cancer of the lip or any of its allied forms elsewhere on the body in their early stages with x-rays. These

FIG. IV. — Large ulcer over right temple and ear covered by flap from scalp. Extensive Tiersch grafting of scalp.

cases should be treated by prompt extirpation with a careful search with the knife for infected lymphatic glands at the points which the disease is most likely to invade. In regard to rodent ulcer then it remains to consider the value of x-ray therapy in its different phases.

In its earliest stages the disease is usually seen as a small pimple or ulcer situated in the nose or near the lower eyelids. These are so easily and painlessly removed by the aid of subcutaneous injections of cocaine, with the knife, that it seems hardly necessary to consider the influence of the rays upon them. Such wounds are healed in a week's time and the cure is, with extremely rare exceptions, permanent. The same may be said of growths ranging in size up to that of a quarter of a dollar, unless they happen to be so situated that their removal with subsequent suture of the wound would cause considerable deformity. This is the case near the inner angle of the eye or near the alæ of the nose or on the nose itself. Experience shows that the cicatrization following the absorption of the growth by the x-ray leaves a soft and pliable scar. If, however, the ulcer is growing rapidly and shows thickened base or edges the stage of increased malignancy is close at hand. When once the inner canthus of the eye has become involved the growth spreads with much greater rapidity into the orbit. We have then a condition which only the most radical operation can hope to control, operations frequently involving extripation of the eye and of considerable portions of bone. At the outer canthus we also see ulcers becoming adherent to the adjacent bone, which is here quite superficial. The x-ray therapeutist should therefore make himself thoroughly familiar with the more advanced and malignant phases of rodent ulcer if he wishes to make an intelligent selection of cases for treatment. There are one or two cases under this treatment shown you this morning which would be better treated by the knife. In such cases the dread of the knife should be overcome and patient be prevented from yielding to his instinct to lean towards the more popular therapy. There are others, however, which show clearly the great advantage which we possess in the ray treatment. There are those cases in which the disease is superficial and spreading over a large surface and those where ulcers are multiple and on prominent portions of the face or closely grouped together so as to necessitate the extirpation of a large piece of skin. In private practice where all such ailments are attended to in their early stages I think that the large majority should be treated by excision and that the x-rays should be reserved for exceptional cases only. The x-ray treatment is tedious and expensive and a severe trial to the strength of nervous and elderly people, who must be prepared to go out in all weathers for a considerable length of time. Some portions of the diseased growth must be allowed to continue in its course from twelve to fifteen months before it yields to the ray. During such a long period of time it might pass from the benign to the malignant stage and then be beyond the pale of surgery. I have seen many such cases dangerously near the border line and feel that a note of warning is necessary to physicians who yield too readily to the popular demand for ray therapy. I have been told recently by a skilled and experienced x-ray therapeutist that he has noticed a recurrence in several cases which he had regarded as cured, the disease returning some months later as a small nodule beneath the skin.

When we realize what frightful deformities may be produced in course of time by what is at first a painless and apparently trifling affection, is it not our duty to urge the most radical treatment in the beginning when a permanent cure is easily obtained?

[1] Dr. F. S. Burns, Boston Med. & Surg. Jour., Oct. 29, 1903.

In closing I would like also to enter a plea for more radical operations for cancer of the lip than are usually performed. Not only should the disease be removed by a most liberal V-shaped incision, but this primary lesion should be dissected away in a continuous mass with the cervical glands and tissue occupying the triangle nearest the seat of growth. The practice of incomplete "ambulatory" operations with the aid of cocaine anesthesia cannot be too strongly condemned.

Original Articles.

THE PREVAILING CONCEPTION OF DEGENERACY AND DEGENERATE, WITH A PLEA FOR INTRODUCING THE SUPPLEMENTARY TERMS DEVIATION AND DEVIATE.

BY G. L. WALTON, M.D., BOSTON.

THE term "degenerate" is now of interest not only to the anthopologist, but to the medical and general public, and the time has come to question whether it is adequate with no synonym, except for its worst significance, to meet all requirements of scientific classification and discussion, to say nothing of general use. If the word had received a uniform and accurate interpretation, the attempt to present an alternative would be superfluous. Such, however, is far from being the case. Degeneracy has become especially associated with profligacy, perversion, crime, epilepsy, insanity and idiocy. This is not remarkable in view of the nature of the word itself. The term "superior degenerate" has led to confusion, even among special students of the subject. While this term in its academic sense applies only to individuals lacking psychic balance, meaning that the higher qualities are affected, the tendency has crept in to include under it individuals with minor congenital peculiarities, whether physical or mental. But to designate an individual possessing either minor faulty mental tendencies or slight physical defects, a superior degenerate, sounds, except to the special student, something like calling a good egg slightly bad, or a business man moderately dishonest. And if in justification, not to say apology, for this diagnosis, it is stated that every one is more or less degenerate, the natural deduction is that the expression degenerate is of no special significance, or that we are only juggling with words, as one who would say "Every one is insane" or "Genius is a sign of insanity."

The works of Nordau [1] and of Lombroso [2] have so far associated degeneracy with decadence and with crime as seriously to hinder the general appreciation of its milder significance, notwithstanding its use in dealing with genius.

Degeneration in its anthopological sense is defined in the Century Dictionary as "reduction to a lower type in the same scale of being; the act of becoming, or the state of having become, inferior, *especially with respect to moral qualities.*"

The superior degenerate who seeks consolation in Roget's Thesaurus will be disappointed to find degeneracy marshaled in company with depravity, demoralization, retrogression, deterioration, perversion, prostitution, vitiation, contamination, corruption, blight, rottenness and pollution.

But degeneracy has come to include, medically speaking, every form of constitutional variation, however innocuous, from the average normal.

Dana [3] defines degeneration as "a condition in which there is a marked deviation from the average normal." Church and Peterson [4] define the stigmata of degeneration as "anatomical or functional deviations from the normal, which in themselves are usually of little importance as regards the existence of an organism, but are characteristic of a marked or latent neuropathic disposition."

The neurological definitions make no mention of moral qualities, and convey no suggestion that the individual necessarily represents a descent, even in the physical or intellectual, to say nothing of the moral, scale. Nor is it a logical conclusion that each and every deviation is degenerative because undoubted degenerates show many such signs. These stigmata range all the way from flecks on the iris, difference in color of the two eyes, unusual development of frontal lobes, left handedness and astigmatism, to perverted instincts, insanity and idiocy. Whatever they may or may not *represent*, the question in recording them is, What *are* they? It seems that they are neither more nor less than deviations from the average normal type. This type is a product of deduction rather than of experience, a composite photograph, so to speak, presenting the intellectual and moral as well as the physical characteristics of the average normal individual, a type not likely to present itself to the material eye, but none the less available for a standard. Goethe calls this standard an "abstract and general image."

Have we not, then, drifted into the unscientific position of recording *facts* in such a way as to involve an *opinion?* If so, is it not reasonable, unless we are dealing with obvious and undoubted degeneracy, to record deviations as deviations? If it is necessary to characterize their possessor, why not call him slightly, moderately or extremely deviate, or, if it seems appropriate, a deviate? And if occasion requires the use of a single word to include all varieties, is not deviation more appropriate than degeneration? Even suppose it can be proved that every deviation means degeneration, will anything have been lost by following a logical plan in establishing that proposition?

We are not limited to the word insanity in

[4] Church and Peterson: Nervous and Mental Diseases. Saunders & Co.

describing borderland dwellers, or the eccentric individuals on the safe side of the border (though it is true that the alternatives have not always been freely used in analyzing genius).

Not every physical peculiarity is truly degenerate; for example, while albinism may be justly regarded as degenerative, in that it implies absence of a useful constituent in the organism, a mere difference in color of the eyes is not necessarily degenerate, though it must be, and so is, classified under the present method, as would, in fact, an absence of appendix if some individual should be born so happily constituted!

If the subject had not become a matter of general interest, the present limitation of our vocabulary would be less objectionable, though even if the discussion were confined to anthropological circles it would seem fair to propose an alternative which should allow a statement of facts in dealing with facts. But since the interest in this subject has broadened, and the public is expected to accommodate itself to the scientific nomenclature, is it too much to make the slight concession of introducing a term which not only does not clash with the facts, but which, if the position is well taken, is really demanded for the accurate presentation and classification of these conditions for scientific purposes?

Degeneration is attributed by Nordau to constitutional disease, alcoholism, poor nutrition and allied conditions in the ancestry; but Vaschide and Vurpas [5] attribute the stigmata to toxic infections affecting the developing embryo. Without pausing to discuss either of these opinions, we may fairly use them as illustrating the different interpretations which have been given the term degeneracy.

Why not, then, incorporate into our vocabulary, for use in its appropriate place, a term which shall give an idea of the accepted facts rather than one which presupposes a definite etiology and tendency? Do not the words deviation and deviate fairly accomplish this end?

Some such nomenclature is especially appropriate in view of the fact that the question is sometimes an open one whether the possessor of moderate stigmata represents a lowering even in the intellectual or physical scale. He may, in fact, represent an improvement, at least on his traceable ancestry.

Nor do the stigmata themselves necessarily indicate deterioration. Extreme dolichocephaly is included in the literature as a stigma of degeneration. Lombroso, for example, cites cephalic indices of 69, 73 and 74. But the fact has been established that dolichocephaly is more common in the city than in the country, an observation to which the name Ammon's law has been applied. Certain authorities have even drawn the conclusions that the long-headed type is the one best fitted to meet the exigencies of city life, and that its prevalence in the centers of population represents a "survival of the fittest." [6]

[5] Ann. di Nevro., Feb. 1, 1903. Abst. in Rev. of Neurology and Psychiatry, June, 1903.
[6] Macpherson: Review of Neurology and Psychiatry, February, 1903.

To cite a more striking instance — Lombroso includes under the physical stigmata of degeneration, in men of genius, the usual development and complexity of the third frontal convolution, especially on one side. He quotes the work of Herve [7] on Broca's convolution, in substantiating this observation, and further cites the morphological complexity of Broca's convolution in distinguished men, as described by R. Wagner, [8] and especially remarks the enormous size and numerous superficial folds in this region in the case of a jurist distinguished for oratorical aptitude.

The downward is not, then, the only direction, as the word degeneracy would imply, in which deviation may be found. Even Lombroso [9] does not claim that every genius is, as a whole, necessarily deteriorate. In fact, he warns against the exaggeration of deducing degeneration from single facts, though he has no other name for the most trivial of those facts than signs of degeneration.

If the ideal average normal individual, to whom reference has been made, could be galvanized into existence, his average normal modesty would surely make him hesitate to rank himself above all the geniuses to whom the term degenerate has been applied.

We sometimes meet acuteness of a special sense so remarkable that it suggests reversion even to a sylvan ancestry, rather than family decadence in the sense in which Nordau uses the term. The abnormal responsiveness to stimuli, sometimes seen in the so-called superior degenerate, reminds us of a similar tendency on the part of lower animals, a tendency representing in their case a survival of the fittest in eluding danger, rather than a sign of decadence. Even here, though it is true that the human being possessing these traits is apt to be so ill-balanced as to rank below the average normal, the term deviate would amply fill the requirements.

It would surely answer every purpose to substitute the word *deviation* in such statistics as those of Lombroso,[10] which state 4% of normal individuals have five or more signs of *degeneration*, as compared with 27.4% of delinquents

The words crime and criminal are supplemented by offense and offender, deliquent and delinquency, and nothing is now proposed more radical than similar alternatives for degeneration and degenerate. No one, I fancy, has ever objected to the word delinquent in the statistics just quoted, though this word is there intended to include the most hardened criminal, while degeneration is obliged in the same table to include the most insignificant signs of deviation.

Among the different factors entering into the question of heredity Mercier [11] calls attention to the wide difference between the children born of similar and those born of dissimilar parents. As

we approach the greatest possible similarity (namely that of marriage among members of the same immediate family), the tendency becomes greater to produce the lowest type of degeneracy. On the other hand, the greater the dissimilarity between the parents up to a certain point, the greater the tendency to produce an organism more vigorous than, and superior to, either of its parents. In the latter case there is also marked tendency to atavism. As the dissimilarity increases we may apparently look for precocity, rapid and exceptional intellectual development, together with the instability characteristic of the so-called superior degenerate. Great dissimilarity leads to wildness in the offspring, and extreme dissimilarity results in sterility. Mercier illustrates the tendency to atavism in fowls of dissimilar parentage, by Darwin's experiment of crossing the black Spanish with the silk-white fowl, and producing in the progeny a red plumage not appearing in either branch, excepting in the wild ancestor common to both. Here we have a stigma of far different type and bearing from the mental and physical results of inbreeding on the one hand, and the atavistic criminal tendencies of Lombroso on the other, neither, meantime, being of parallel significance, with the evolutional spurt seen in the remarkable development of Broca's convolution in the individual with unusual command of language. And a still further type is found in the results of infection in the embryo. If one term must be chosen to include all types with their modifications and gradations, it seems unfortunate that a name should be chosen which has, of necessity, a sinister significance, by no means uniformly appropriate. In the light of such considerations the use of the term deviation may even contribute toward a better understanding of the complex conditions with which we are concerned. And even if the word fails of adoption, the discussion will at least tend to clear the atmosphere and to lessen the resentment inevitably aroused by the word degeneration.

Even certain illustrious sufferers from convulsions, and allied serious signs of constitutional taint, have possessed intellectual qualities so far superior, not only to the average, but to the best, that their careers have made epochs in history. And, to cite one from many possessors of less serious signs, what shall we say of Carlyle, who as a boy was shy, proud and pugnacious, with strong affections and violent antipathies, whose indigestion and whose eyestrain have been in turn deemed the cause of his unfortunate disposition, all, whatever their interaction, being probably only signs of a constitutional make-up which included a psychopathic endowment? In later life he became so highly sensitized as to declare war upon his neighbor's poultry, and to have constructed a sound-proof room for his labors, labors which were themselves upon the highest intellectual plane. Must we call him a superior degenerate?

The very expression superior degenerate is anomalous, for if we still deem the individual inferior to the normal, superior is an inappropriate qualification to apply, and if we deem him equal or superior to the normal, the term degenerate is unfortunate. Indeed the expression almosts suggests the query, if a superior degenerate is less degenerate than an inferior degenerate, what degree would the supreme degenerate represent?

The term deviation may cover all variations from the average normal, whether above or below, or at the same level, in the intellectual, physical, moral or other scale. Nor need it necessarily be limited to the lighter grades of variation, but we may have, if you like, the minor and major deviate, whereas, the more appropriate the term degeneration when applied to stigmata, to individuals, to families, or to races showing unquestioned downward tendency, the more reason there is for keeping the word within its proper limitations, and especially of replacing, as far as practicable, that self-contradictory and unnecessarily opprobrious designation, superior degenerate.

CANCER OF THE RECTUM: COMBINED ABDOMINAL AND PERINEAL OPERATION.[1]

BY CHARLES A. POWERS, M.D., DENVER, COL.,

Professor of Surgery in the University of Denver; Surgeon to St. Luke's Hospital.

That the attempt at thoroughness which characterizes present operative procedure for cancer of the breast, lip, uterus and other organs, is extending to operations for cancer of the rectum seems to be manifest from the recent writings of Abbe, C. H. Mayo, Weir, Kocher, Kraske, Graudier, Quenu, Trendelenberg, and others. No better exposition can be made of the dissatisfaction which surgeons have felt with perineal and sacral methods in high-seated rectal cancer than that of Mayo in the *Journal of The American Medical Association* for April 25, 1903, nor can a better plea be offered for the combined abdominal and perineal operation (which Mayo attributes to Gaudier of Lille) than that set forth by him. This latter procedure has the advantage of permitting the operation to suit the case: either a palliative colostomy or the radical removal of the growth *en masse* with incisions wide of the growth itself and embracing all glands, fat and connective tissue; together with this the retention of the sigmoid as a fecal container and the placing of a permanent anus in the iliac region where it is most easily borne and managed by the patient.

Errors of technique in the single case reported herewith may be of service to others who undertake the procedure. At the risk of being tedious the case itself is given at some length. It is presented at this early day purely as an operative illustration. I believe it to represent a type of operation which will gain in favor.

Case. Mrs. W. Native of England. Forty-five years of age.

Previous history. — The patient has borne four chil-

[1] Read before the Colorado State Medical Society, October, 1903

dren, having no special trouble with any of them. She has had no symptoms referable to the genital tract. She was a well and strong woman up to six months ago, at which time she began to suffer from increasing constipation which was difficult to overcome by medicines. She found that her stools were getting smaller and painful, that a mucous rectal discharge began to appear. She went to a physician, who prescribed ordinary remedies. The difficulties increased, it became more and more troublesome to move the bowels and she began to lose in weight and strength. A little while ago she consulted Dr. M. Baker, who discovered a tumor of the rectum and kindly recommended her to me.

Present condition. — April 4, 1903. The patient is a rather spare woman five feet one inch in height. Her color is fairly good, she looks to be about forty-five years of age. Careful examination of the heart, lungs, kidneys and liver fails to disclose evidence of disease. Her appetite is fairly good, she eats moderately and digests well but has much difficulty in overcoming a chronic constipation. She says that the stools are small, ribbon-like, painful; that they are occasionally tinged with blood; that during the past few weeks there has been a thin rectal discharge. The bladder has given no trouble.

Local Examination. — A little above the anus there is an irregular, hard, nodular mass involving the circumference of the bowel and admitting with difficulty the end of the index finger. The finger crowded well up engages in the tumor. The tumor is movable and not particularly painful. The lower portion of it can be felt through the vagina, but the finger behind the neck of the uterus fails to define the upper limit of the mass. The uterus is in a posterior position, the tubes and ovaries are apparently healthy. Abdominal examination is negative.

Diagnosis. — Cancer of the rectum extending high. In view of the high seat and the good general condition of the patient combined abdominal and perineal excision was decided upon and the patient was carefully prepared with this in view.

Operation. — St. Luke's Hospital, 8:30 A.M., April 11, 1903. Chloroform was skillfully administered by Dr. F. W. Kenney. A short gridiron incision at the outer border of the left rectus permitted the introduction of an exploring finger. The rectal mass was felt low down. It was movable. No enlarged glands could be felt. Gauze packing was introduced into this incision. A median incision was rapidly made from the umbilicus to the pubes, the patient put in a high Trendelenberg position and the intestines carefully packed off. The uterus was drawn forward beneath the pubes. With wide lateral retraction the rectum was in easy view. It was again examined, confirming the exploratory palpation. A point in the sigmoid flexure was selected a little above the brim of the pelvis and the gut milked free of contents. Two heavy purse-string sutures of silk (according to Abbe) were rapidly applied; these were about two inches apart and involved the muscular coats of the gut. Midway between these purse-string sutures the gut was cut square across, the mesentery split down a little and the mesenteric vessels tied. Each end of the gut was then inverted and the purse-string stitches tightened. This completely shut off the lumen of each end of the gut from the operative field. Local packing was rapidly removed, the field sponged out, fresh packing applied and the instruments used in dividing the gut discarded. A comparatively clean operative area containing the two blunt rectal ends was now present. The lower end of the upper fragment was ready at any time to be brought out through the exploratory wound as an artificial anus. The mesentery of the upper end of the lower fragment was then divided downward until a point was reached at which the peritoneum began to shade off on the rectal sides. Here the peritoneum was split down a little on each side of the gut and then divided anteriorly. Below this point it was peeled up with a blunt scissors and the finger, thus rapidly separating the rectum. Posteriorly the superior hemorrhoidal artery was felt. This was doubly ligated; first with heavy catgut, after which the open mouth was picked up and tied with fine silk. Up to this point there had been but very little bleeding and from this time on the abdominal operative field was practically bloodless. The rectum with its posterior fat, fascia and lymphatics was cleanly dissected from the hollow of the sacrum and worked free to the lowest possible point. This was about on a level with Douglas' cul-de-sac. An assistant now passed a long dressing forceps through the vagina up behind the neck of the uterus. The point of this was cut upon from the abdominal side, the vaginal wound enlarged, the upper end of the segment of the rectum and the entire mass which had been dissected free being caught and dislocated into the vagina.[2] The abdominal wound was washed and the pelvic peritoneum stitched up. This peritoneal suture was difficult. It was deep in the pelvis and I had neglected to preserve quite enough peritoneum to allow the edges to come together without tension. For this reason the peritoneal suture took longer than it should have done. When it was completed, however, the pelvic floor presented something the appearance which it does after an abdominal hysterectomy, plus the presence of the uterus.

The lower end of the abdominal gut was brought out through the original lateral opening. The peritoneum on either side of the mesentery had to be cut a little to allow it to come up without tension. The abdominal packing was removed, the abdomen thoroughly flushed and the median incision sewn up. The gut was then rapidly stitched into the lateral opening, first by catgut stitches joining the edges of the parietal peritoneum to the visceral peritoneum. The purse-string stitch originally put in was removed and the mouth of the gut stitched to the skin. An occlusive dressing was applied to the median wound and a separate dressing to the artificial anus.

The patient was now placed in the lithotomy position, the buttocks well elevated, and the remainder of the operation completed from below. The upper portion of the lower fragment of gut was found in the vagina. The vaginal mucous membrane was split in the median line posteriorly and dissected from the rectum on either side. The anus having been sewn up, an incision was made encircling it and perineal excision of the rectum proceeded with from below, cutting widely on either side and posteriorly to the tip of the coccyx, working up in front of the coccyx and hugging it closely. In this way, keeping close to the coccyx and sacrum and dividing the posterior ligaments of the rectum, one was able to work up and meet the upper wound posteriorly. The rectum was then dissected up on either side, moderate downward traction being made on it. This was the most difficult part of the perineal operation; while working rapidly and with considerable traction the peritoneal stitches which had closed over the floor of the pelvis tore out and a loop of small intestine came down. This was pushed back with gauze and the rectum entirely removed. There was a fair degree of hemorrhage at the lower part of the perineal incision but practically none at the upper part. The only vessels which required ligation were the inferior hemorrhoidal arteries on either side. The wound was well flushed and the upper portion explored. An attempt was made to resuture the pelvic peritoneum from below but it was unsatisfactory. The wound was so deep that it was very difficult to get the peritoneal edges. As has been said, they did not come together easily from the abdominal side and as the patient had already been under chloroform over three hours it was judged wise to carefully pack off the pelvis. The vaginal mucous membrane was sewn up and a few perineal stitches put in. The cavity left in front of the sacrum and coccyx was a pretty big one. Laterally it was bounded by the obturator fascia. Its edges could not be approximated. It was lightly packed, in part with sterile gauze and in part with iodoform gauze and an ordinary perineal dressing applied.

The operation had been a long one, practically three hours and a half. The pulse was 72 at the beginning of the operation, it was the same throughout and at its close. But little blood was lost. But 15 drachms of chloroform were used. The patient was a thin and favorable subject and was in good condition. She was at all times under full surgical anesthesia and gave no trouble whatever. She was small of stature and the abdomen and rectum

[2] This mass in the male would be carried downward and backward toward the coccyx.

were particularly accessible. Perhaps fifteen minutes were lost in attempting to replace the peritoneal stitches which had been torn out.

The segment of gut measured 11½ inches in length in the fresh state. Four and three-quarters inches of this was above the upper margin of the tumor. The specimen was given to Dr. J. A. Wilder, pathologist to the hospital, who reports as follows.

"The specimen consists of 11½ inches of rectum with surrounding tissue and lymph nodes. The lumen of the rectum is partially occluded by an irregular nodular mass that begins 2¾ inches above the anus and extends upward 4½ inches, involving the greater part of the circumference of the gut but being at all points well within the lines of incision. There are numerous lymph nodes in the connective tissue behind the segment of gut above the mass but no enlarged lymphatics are found near the upper end of the intestinal fragment. Microscopic examination shows the mass to be an adenocarcinoma. The lymph nodes show cancerous invasion."

The patient vomited pretty constantly for thirty-six hours after going back to bed. Her pulse at the end of thirty hours was 108, it then dropped to 98. Forty-eight hours after operation her stomach was quiet, she was beginning to take nourishment. During the first thirty hours five pints of salt solution were infused.

The subsequent course was smooth. The median abdominal stitches were taken out on the seventh day and at the same time the silk stitches fixing the gut at the site of the artificial anus were removed. The median wound had been kept clean and both wounds healed primarily. The bowels were freely moved on the fifth day. At no time was there abdominal distention. A part of the perineal packing was taken out on the fourth day, a little more each day thereafter and on the eighth day cloroform was given when the vaginal and perineal stitches were removed and the high gauze packing, that which had held the gut in place, carefully taken out. The sacro-perineal wound closed down gradually and completely. The patient began to be up and about in the usual length of time. It is now six months since the operation. She has gained in weight and strength. The artificial anus behaves well; indeed, the fact that the woman satisfactorily pursues the occupation of cook in a private family would seem good evidence of this. The gridiron incision allows a fair "pinch" to the gut.

Clinical Department.

CESAREAN SECTION FOR PLACENTA PREVIA IN A PRIMIPARA.

BY WILLIAM N. SWIFT, M.D., NEW BEDFORD, MASS.

MRS. G. Thirty-four years. Married four years. Good family history. She had previous to her marriage been a school teacher and had been well. Menstruation regular. For six or seven years, rather profuse and with a great deal of pain. During pregnancy she had been well but had considerable abdominal soreness. Had no hemorrhages.

On May 11, 1903, had some abdominal pain and felt generally ill. Slept well that night, but the next morning had more cramps. Some of them quite severe. While sitting in a chair about one o'clock had a severe hemorrhage. It came on without warning and without pain. She said it felt as if something gave way. The hemorrhages continued and patient became faint. Dr. John D. Hilton of South Swansea had charge of the case and called Dr. A. S. MacKnight of Fall River in consultation. Dr. MacKnight made a diagnosis of placenta previa and advised Cesarean section.

I saw the case about ten o'clock. The patient showed the effects of a loss of a large quantity of blood. Her pulse was rapid but regular and of fair quality. The vagina was full of blood-clots with constant flow of fresh blood. The cervix was not entirely taken up and only admitted one finger. A soft mass could be felt through the cervix. The child was a vertix presentation with the back to the right. Immediate section was advised as the only hope of saving the mother and the only possible chance of a living child.

I operated at eleven o'clock, assisted by Dr. A. Martin Pierce of New Bedford and Dr. John D. Hilton. Dr. MacKnight gave the ether.

An incision was made in the median line and the uterus delivered. The uterus was opened on its anterior surface and the child delivered.

The placenta was found to cover the whole of the os, possibly a little more of it being on the right side. The membranes and placenta were at once separated and delivered. The placental site was wiped off with gauze. A gauze pad was packed over the placental site with the end brought down into the vagina. The uterus contracted well. There was almost no loss of blood either from the incision of the uterine wall or the placental site. A continuous catgut suture was put through the uterine mucous membrane and including a little of the uterine muscle. The rest of the incision in the uterus was closed by interrupted catgut sutures through the peritoneal coat down to the continuous suture. The abdominal wall was closed with interrupted silk sutures through all the layers in order to gain time, as the patient's condition was not good. The gauze was taken out without hemorrhage following.

Patient was put to bed in fair condition, having had a hypodermic of strych. sulph. gr. 1-30.

After stimulation and artificial respiration the baby (a girl weighing seven pounds) did well. The mother had very little lochial discharge. Her bowels were moved on the third day. She had very little rise in temperature and did well in every respect. Stitches taken out on the tenth day — one small stitch-hole abscess. Uterus freely movable, not adherent to abdominal wall.

On May 28 the patient had quite a severe hemorrhage. The nurse thought about a quart of blood. Patient was faint and nauseated. The hemorrhage did not recur. Patient is in good condition at present. Has menstruated regularly. The first few times rather profuse with some pain; now, less flow and very little pain. The mother had very little milk and the baby was fed. The baby has done well and is a strong, healthy girl.

My reason for reporting this case is its rarity. The conditions existing in this case, in my opinion, always demand Cesarean section if the patient's condition will permit, that is a primipara, with undilated cervix and central placenta previa. The operation was performed at the patient's house in the country by lamp light.

THE oil painting of Dr. Thomas G. Morton presented to the Pennsylvania Hospital by a number of contributors was unveiled on Jan. 11. The portrait was presented to the hospital by Dr. J. C. Wilson, on behalf of the Board of Trustees, and was accepted for the hospital by Dr. Arthur V. Meigs. Dr. Morton was connected with the institution for a period of forty years, many improvements and new buildings being added during this time as a result of his untiring efforts in its behalf. — *Medical News.*

Medical Progress.

REPORT ON PEDIATRICS.

BY THOMAS MORGAN ROTCH, M.D., AND JOHN LOVETT MORSE, M.D., BOSTON.

(Concluded from No. 2. p. 45.)

REPORT UPON THE RESULTS WITH DIFFERENT KINDS OF PURE AND IMPURE MILK IN INFANT FEEDING IN TENEMENT HOUSES AND INSTITUTIONS OF NEW YORK CITY. A CLINICAL AND BACTERIOLOGICAL STUDY.[5]

THIS very important work was done in New York during the summers of 1901 and 1902 and the winter of 1901. It is impossible to take up in detail the methods employed and the results obtained. The reader is strongly advised to consult the original article which is well worth careful study. A few abstracts from the summary are appended.

" I. During cool weather neither the mortality nor the health of the infants observed in the investigation was appreciably affected by the kind of milk or by the number of bacteria which it contained," the different grades of milk varying much less in the amount of bacterial contamination in winter than in summer.

" II. During hot weather when the resistance of the children was lowered the kind of milk taken influenced both the amount of illness and the mortality. . . . The effect of bacterial contamination was very marked when the milk was taken without previous heating; but unless the contamination was very excessive, only slight when heating was employed shortly before feeding."

" III. The number of bacteria which may accumulate before milk becomes noticeably harmful to the average infant in summer differs with the nature of the bacteria present, the age of the milk, and the temperature at which it has been kept. When milk is taken raw, the fewer the bacteria present the better are the results. . . . Heat above 170° F. not only destroys most of the bacteria present but apparently some of their poisonous products. . . . "

" IV. When milk of average quality was fed sterilized and raw, those infants who received milk previously heated did, on the average, much better in warm weather than those who received it raw. . . . "

" V. No special varieties of bacteria were found in unheated milk which seemed to have any special importance in relation to the summer diarrheas of children. . . . "

" VII. Since a large part of the tenement population must purchase their milk from small dealers at a low price, everything possible should be done by Boards of Health to improve the character of the general milk supply of cities by enforcing proper legal restrictions regarding its transportation, delivery and sale. Sufficient improvements in this respect are entirely feasible in every large city to secure to all a milk which will be wholesome after heating. The general practice of heating milk which is now becoming a custom among the tenement population of New York is, undoubtedly, a large factor in the lessened infant mortality during the hot months."

" VIII. Of the methods of feeding now in vogue, by milk from central distributing stations unquestionably possesses the most advantages, in that it secures constant oversight of the child, and since it furnishes the food in such a form that it leaves the mother least to do and gives her the smallest opportunity of going wrong. . . . "

" IX. . . . Only the purest milk should be taken raw, especially in the summer."

" X. Since what is most needed is intelligent care, all possible means should be employed to educate mothers and those caring for infants in the proper methods of doing this. . . . "

" XI. Bad surroundings, though contributing to bad results in feeding, are not the chief features. . . . "

" XII. The observations indicate that close percentage modification of milk, although desirable in difficult cases, is not necessary to obtain excellent results with the great majority of infants, and that a certain adjustment of a healthy infant to its food is usually soon secured."

THE RELATION OF THE SURFACE AREA OF INFANTS TO THEIR NUTRITIVE NEEDS.

Lissauer[6] carefully measured twelve infants, studied the relation between the nourishment taken and the surface area in others, and thoroughly reviewed the literature. He comes to the following conclusions:

(1) The estimation of the nutritive need according to the weight gives reliable average figures only in infants developed in accordance with their age.

(2) The surface area of infants of the same weight is the same, independent of their age.

(3) The nutritive need of infants of the same age but of different weights is different. It is not proportional to the weight, but to the surface area.

(4) The nutritive need of infants of different ages but of the same weight is different even if the surface area is the same. The older infants who are backward in their nutrition have a much greater need. This need corresponds to that of the normal infants of the same age.

(5) The greater need of the backward older infants in comparison to the younger infants of the same weight is due to the relatively greater number of active cells, the fat tissue not having been formed on account of the backwardness of the nutrition.

(6) The differences in the nutritive need observed in infants of the same age and weight may perhaps be explained in the same way.

THE SERUM TREATMENT OF TYPHOID FEVER IN CHILDHOOD.

Josias[7] states that the antityphoid serum of Chantemesse shows in animals anti-infectious and

[5] Wm. H. Park, M.D., and L. Emmett Holt, M.D.: Archiv of Pediat., 1903, v. xx, p. 881.

[6] Jahrb. f. Kinderh., 1903, v. lviii, p. 393.

[7] Rev. d'Hyg. et de Med. Infant., 1903, v. ii, p. 209.

antitoxic properties. It acts especially by increasing the activity of the phagocytes and leucopoietic organs. It therefore shows its whole power only when the lymphoid and the myeloid organs are intact. For this reason the serum is most useful at the beginning of infection. For the same reason small doses only can be given when the intoxication is severe. He then quotes Chantemesse's results with his serum in adults.

He used Chamtemesse's serum in 50 cases of typhoid fever in children at the Bretonneau Hospital in Paris. He gave 1 cc. of the serum per each 30 kilos of body weight when the cases were seen at the beginning. Half of this dose was given when the cases were seen late or the symptoms of intoxication were very marked. In most cases only one injection of the serum was given. The children were also given cold baths. In all cases the diagnosis of typhoid was confirmed either by a positive Widal reaction or by rose-spots.

The serum had a definite action on the course of the fever. Ordinarily a more or less marked decline showed itself the same day. The fall of the temperature often continued regularly and rapidly to complete recovery. In most cases the serum hastened the termination of the disease. In certain severe cases which were treated late the serum apparently had no rapid action either on the temperature or on the duration of the disease. In most cases the general condition of the patients was very satisfactory. In a number of cases in which the injection of the serum was quickly followed by the fall of the temperature to normal there was without any apparent cause a sort of recrudescence of the disease of moderate severity and stopping spontaneously in from five to ten days. In four cases there was a definite relapse. Complications were exceptional. One case had peritonitis with perforation. Twenty-four of 169 children treated in other hospitals in Paris during the same time died, giving a mortality of 14.2%. Two of the 50 cases treated by the serum died, giving a mortality of 4%.

BACTERIURIA IN CHILDREN.

Mellin [8] was able to find in a search through the literature only 11 cases of this condition. Ten of these were in girls. He, himself, when he looked carefully for this condition, found 10 cases in a year. He thinks that the reason it has been found so seldom is that the physician rarely has the opportunity to get the fresh urine. Five of his cases were in boys, and 5 in girls. Nine of the children were between five months and four years of age; the other was ten years old. Bacteriuria seldom causes in children general symptoms such as fever, discomfort, vomiting and so on. It is accompanied somewhat oftener by slight and usually fleeting fever. Still more frequent are the mild cases in which the disease shows itself only by frequent micturition or by the odor and cloudiness of the urine. In these latter cases subjective symptoms are often entirely wanting. Intestinal disturbances are often associated with bacteriuria in children, and probably stand in a causal relation. In one of his cases the disease was secondary to an abscess about the anus and was cured when the latter was incised. All the earlier cases were due to the colon bacillus. He found this organism in eight of his cases, and the staphylococcus pyogenes albus in the other two. As a rule he found that the virulence of the bacteria to animals was slight.

The treatment of bacteriuria is simple. In the lightest cases regulation of the diet and the relief of the intestinal disturbance is sufficient. In the more severe cases he advises salol and irrigation of the bladder.

RESEARCHES ON SOME FORMS OF SENSIBILITY AND ON THE STEREOGNOSTIC SENSE IN CHILDHOOD.

The authors [9] studied the interesting problem of the state of the tactile, thermal and pain sensations in infancy, as compared to adult life, as well as the development in infants of the so-called sense of location and position. As yet but few studies of similar character have appeared, and the present article offers the results of continued observations in a number of children. They found that the tactile sense was highly developed in children from two to eight years of age, with a very precise localization and limitation of the tactile circles. The sensation of pressure and that of heat were fully developed. The so-called muscular sense or the sense of attitude and the power of stereognostic perception were exact and precise. The sense of pain, however, as tested with the electric current, was deficient as compared to its development in the adult, and the authors conclude that this sense is a differentiation which occurs later in life through a probable summation of the general sensibility.

GONORRHEA IN INFANTS, WITH A REPORT OF EIGHT CASES OF PYEMIA.

Kimball [10] reports eight cases of pyemia in infants. Microscopic examination of the pus obtained from various joints showed in all cases diplococci with all the characteristics of gonococci and no other organisms. In six cases cultures of the gonococcus were obtained. In two others negative results were obtained on ordinary media. Autopsies were made in three cases. None of the usual local lesions could be found to explain the mode of entrance of the organism to the general circulation. There was a stomatitis in three cases. Kimball thinks that this stomatitis may have been gonorrheal in character and the source of infection. In another case a respiratory source of entry was strongly suggested by the post-mortem findings.

APOPHYSEAL OSTEITIDES OF ADOLESCENCE.

Comby [11] draws the following conclusion from the study of several cases:

[9] Cattaneo, Cesare and Marimo, Francesco: Pediatria. December, 1903, p. 993. Abstr. in Archiv of Pediat., July, 1903, p. 552.
[10] Med. Rec., 1903, v. lxiv, p. 761.
[11] Arch. de Méd. des Enfants, v. vi, p. 533.

In late infancy and adolescence there occurs in children who grow quickly a mild ostitis which especially affects the anterior superior tuberosity of the tibiæ. This ostitis is perhaps more common in girls than in boys. It usually is symmetrical but sometimes is unilateral or more marked on one side. It shows itself by a swelling appreciable both by sight and palpation but without heat or fluctuation. The chief symptom is pain. This pain occurs even during repose but is increased by motion, walking and pressure. There is no fever; the appetite is preserved; the general condition not affected. The duration may be long, but the disease always ends in resolution. The disease is easily recognized. The most efficacious treatment is rest in bed during a week, or more if that is necessary, and the application of iodine. When the patient gets up fatigue should be avoided. The food should be nourishing. Cod-liver oil and the glycerophosphate of soda are recommended.

IODOPHILIA IN DIPHTHERIA.

Weiss [12] examined the blood for the iodin reaction in 52 cases of diphtheria. He arrived at the following conclusions: The iodin reaction is not pathognomonic for diphtheria. It is absent in all mild cases and occurs only in the severe cases of diphtheria of the throat and larynx. When present it is due to the considerable infiltration of the tissues of the throat or neck or to disturbance of the respiration. These causes are demonstrable and amply sufficient to account for the phenomenon, and thus stand in marked contrast to the action of toxines, which can hardly be proved.

THE LEUCOCYTOSIS OF MEASLES AND GERMAN MEASLES.

Plantenga [13] examined the white corpscles in a considerable number of cases of measles and German measles. He found in measles a considerable hyper-leucocytosis of the polynuclear neutrophiles during the period of incubation. This hyper-leucocytosis was followed by an equally large hypo-leucocytosis of the polynuclear neutrophiles during the last days of the enanthem and during the exanthem. Occuring at the same time with this hypo-leucocytosis there was sometimes during the periods of the enanthem and exanthem a marked lymphocytosis. This was always accompanied by violent and persistent diarrhea as well as by a general enlargement of the lymph nodes. After the exanthem the number of leucocytes returned to the normal. If they did not there was some complication present. The same modifications of the blood were found in German measles as in measles.

He concludes that because of the identical blood conditions examination of the blood is of no use in the differential diagnosis between measles and German measles. The results obtained by the examination of the blood in measles and German measles are entirely in favor of the old idea that the two diseases are one and the same.

ACUTE AMAUROSIS FOLLOWING INFANTILE CONVULSIONS.

The authors [14] describe a series of cases of amaurosis, which they believe to be directly due to severe convulsions. Thus, the infants develop a series of convulsions with coma (resembling the status epilepticus of adults) and upon recovery are found to be blind and sometimes to be hemiplegic or aphasic. There was no evidence of meningitis. Ophthalmoscopic examination yielded negative results. They distinguish this form of blindness from the amaurosis, also without ophthalmoscopic signs, which may accompany or follow posterior basal meningitis in infants. They conclude (1) that there is a form of post-eclampsic amaurosis due to anesthesia of the visual centers, occurring in infants; (2) that the convulsions, which may be due to various causes, are apt to be severe and accompanied by coma; (3) that the amaurosis may be associated with aphasia of hemiplegic distribution; and (4) that the amaurosis is for the most part transient.

Reports of Societies.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

PROCEEDINGS OF THE SIXTEENTH ANNUAL MEETING, HELD AT THE PIEDMONT HOTEL, ATLANTA, GA., DEC. 15, 16 AND 17, 1903.

THE President, J. WESLEY BOVEE, M.D., Washington, D. C., in the chair.

A STUDY OF THE PROSTATE AND TREATMENT OF PROSTATIC HYPERTROPHY.

DR. G. WILEY BROOME, St. Louis, Mo., showed a number of hypertrophied prostates that he had removed. Approximately, he had made two hundred post-mortem examinations to investigate the condition of the bladder and prostate in each subject. He said it was generally maintained by routine prostatectomists that all prostates had a capsule, but this was not true.

He drew the following conclusions: (1) The position of the urethra in the normal state was always in the floor of the bladder; but in cases of urinary obstruction it was always elevated from an inch to an inch and a half or two inches above the floor of the bladder. (2) Normally there was no third lobe, but that segmentation took place behind the prostatic fissure in consequence of a hyperplastic process, this process occurring in the direction of least resistance — into the cavity of the bladder. (3) Only a small percentage of cases of hypertrophied prostate was responsible for urinary obstruction. (4) No matter how large the prostate became, it would retain

[14] Dr. Henry Ashby and Mr. Sydney Stephenson: Pediat., June, 1903, v. xv, No. 6, p. 348.

its functionating capacity. It was not the prostate which caused suffering to the patient. (5) By prostatectomy this functionating organ was mutilated or destroyed, and the bladder, which really caused the patient trouble, was left *in situ* without any operation having been performed on it. (6) In only a small percentage of cases could the prostate be enucleated. (7) It was unfortunate that the profession had reached the point of resorting to routine prostatectomy in all cases of urinary obstruction. (8) The commissure and capsule were obliterated in the fibromyomatous variety of prostate. In the adenomatous variety, if complete and permanent drainage was established, the prostate would shrink.

DR. C. H. MAYO, Rochester, Minn., had operated by the median perineal method in over thirty cases after the manner of Goodfellow, and had been much pleased with the method and results.

DR. W. P. CARR, Washington, D. C., had seen only one prostate where there was any difficulty in peeling it out of its capsule. Cases of hypertrophied prostate should be operated upon earlier, before the bladder became infected. Prostatectomy in healthy men had a very small mortality, but in those who had infected bladders, who had Bright's disease, or atheromatous arteries, it was a serious operation.

DR. BROOME, in closing, deplored the tendency to do routine prostatectomy regardless of the actual pathological conditions of the parts.

EDEMATOUS ENCEPHALITIS.

DR. W. P. CARR, Washington, D. C., called attention to a condition of the brain that he had encountered quite frequently when operating for cerebral epilepsy and for suspected cerebral abscess following mastoid disease due to influenza. This condition he called edematous encephalitis. It was apparently so much benefited by opening the skull and draining the excessive serum from the brain, that it deserved careful consideration. He reported four cases. In cases of severe cerebral symptoms following influenza or blows upon the head, where the symptoms persisted or became worse after weeks of medical treatment, he thought that exploration was justifiable in the hope of finding edematous encephalitis or some other condition that would be benefited by operation. In operating for edematous encephalitis he recommended that a large osteoplastic flap be cut with the De Vilbiss craniotome over the site of any injury that might be suspected as a cause, or over some location indicated by the symptoms. If the symptoms furnished no local indication, and there was no local injury, then the flap had best be turned down in a convenient place, say the upper parietal region. The exposed membranes and brain substance should be examined carefully, and if they presented an edematous appearance a grooved director should be introduced into the brain substance carefully in several places, and the serum drained off until the brain assumed a normal appearance. A small soft drainage tube should be inserted just through the dura into the arachnoid space and left in place as long as there was a copious discharge of serum. This tube might be brought out through one of the small trephine holes made for the introduction of the De Vilbiss instrument, and stitched to the skin after an osteoplastic flap had been replaced. If the head was carefully shaved and scrubbed, and all proper antiseptic precautions taken, this operation was almost free from danger; and if only a small percentage of the serious cases could be cured in this way, the operation would be justifiable. He had been encouraged by his limited experience to believe that surgeons might hope for recovery or great improvement from this operation in many otherwise hopeless cases of epilepsy and of progressive brain disease due to trauma and influenza.

A NEW DEVICE AND METHOD FOR INTESTINAL ANASTOMOSIS.

DR. CARR said he had devised a method of intestinal or gastro-intestinal union by small silver clamps, which he thought were more easily and quickly applied than the Murphy button. These clamps were exhibited. He had used them in one case of resection of five inches of gangrenous ileum caused by strangulated hernia. The man recovered and the clamps were recovered between the sixteenth and twenty-first days.

DR. C. H. MAYO said he and his brother had operated on many cases of epilepsy and traumatic insanity, and he could corroborate what the essayist had said regarding edematous encephalitis. Treatment by drainage came the nearest to the solution of affording this class of cases relief.

DR. I. S. STONE mentioned a case, in referring to Dr. Carr's clamps, in which gastro-enterostomy was performed about a year ago, with the aid of the Murphy button, but the button had not yet been passed.

In another case of diverticulum with obstruction, the button was used, but the woman was still carrying it with some anxiety. Thus far, however, there were no symptoms of intestinal obstruction from the retention of the button.

DR. GUY L. HUNNER objected to the use of all mechanical devices and favored suturing the intestine, although he thought the simple device exhibited by Dr. Carr would enable surgeons to do intestinal anastomosis rapidly.

DR. J. GARLAND SHERRILL advocated suturing the bowel in preference to the use of mechanical aids. In his intestinal work he preferred silk.

THE SURGICAL PHYSIOLOGY OF THE LYMPHATIC SYSTEM.

DR. C. H. MAYO, Rochester, Minn., said that a study of the lymphatic system readily explained many normal physiological as well as pathological processes. All tissues were provided with lymph vessels and glands in direct proportion to their exposure, activity and necessity for repair.

The tissues of the body were constantly bathed in lymph, which fluid, similar to and derived from the blood plasma, must all pass through the lymph vessels and glands. In the glands the lymph was exposed to the direct action of the leucocytes which were there found in great abundance. It was in the glands that infection was checked, and destroyed, or it might possibly overpower the glands and develop local growth. An enlarged gland was an evidence of a local struggle and a defeat. The lymph system undoubtedly performed a great function in draining the ductless glands.

Considering the lymph supply of certain organs, it was found that the brain was deficient in lymphatics in its structure, the arachnoid serving this purpose upon its surface. Hemorrhages into its structure became cysts from lack of absorption and infections of its substance caused but little temperature or general disturbance except from pressure. Liver and kidney showed the same condition in a less marked degree.

The lungs, rich in lymphatics, gave constant temperature from infectious diseases. Chills usually signified the direct delivery of accumulations of infection into a vein. In certain diseases resulting from a loss of equilibrium between the production and absorption of fluids, one set of lymphatics was substituted for another by operation, as in glaucoma and hydrocephalus.

When lymphatic conditions were considered in connection with surgical work, it was found that there was a real principle involved in drainage, whether it be internal or external.

Dr. Mayo then discussed the varieties of drains and drainage adjuncts.

EARLY DIAGNOSIS OF CANCER OF THE UTERUS.

DR. F. F. SIMPSON, Pittsburg, Pa., said that early in 1900 a note was addressed to the health departments of American cities with an aggregate population of ten millions, requesting a tabulated statement of deaths from cancer and from all causes during each year of the preceding decade. Statistics showed that of every fourteen people who reached the age of thirty, cancer would claim one as its victim. Bearing more directly upon the subject of cancer of the uterus, however, was the distressing fact that of every twenty-eight women who passed the age of thirty, one would be the victim of this disease.

The paper was largely statistical, and the author closed by saying that the day was fast approaching when well-informed women of the cancer age would seek protection by regular quarterly examinations. Early diagnosis would then be the rule in cancer of the uterus as it was in appendicitis to-day.

FRACTURE-DISLOCATION OF THE SPINE.

DR. J. SHELTON HORSLEY, Richmond, Va., reviewed the opinions of several authorities on the treatment of this lesion. He advocated the plan of McCosh to operate in all cases of complete paralysis below the injury unless there was improvement within twenty-four hours after the injury. When the trauma was especially marked, he operated sooner. He pointed out that the danger of delay lay in degenerative changes in the spinal cord which set in soon after the injury. Early operation might arrest this degeneration.

He reported six cases, in two of which the injury was received several years before he saw the patient. In one there was a forward dislocation of the axis and atlas from the third cervical vertebra. This was demonstrated by a skiagraph. The patient had paralysis of the muscles of the arm, body and thighs. There were disturbances of sensation of various degrees over the body and limbs. He reported two other cases in which fatal results rapidly followed the injury. One was from a gunshot wound and the other was the result of a fall on the shoulder in which there was a fracture-dislocation in the lower dorsal region. In one of the last two cases he operated upon there was an injury at the lower dorsal region where the whole of the dorsal spinal column was dislocated forward upon the lumbar spinal column. The spinous process of the last dorsal vertebra was fractured. The cord was caught between the last dorsal and the first lumbar as between the blades of a pair of scissors. It was not completely crushed, as the dislocation was not extensive enough. It was impossible at the operation to reduce the dislocation, so the spinous processes and the laminæ of the last three dorsal vertebræ were removed. This relieved the pressure on the cord. The patient died, however, from pneumonia a week later without any improvement in the spinal symptoms. A post-mortem examination showed the wound in an excellent condition, with the cord softer than at the time of operation, and solidification of the whole lower lobe of the right lung, and a part of the middle lobe. In the other case operation was undertaken about a month after fracture of the eleventh and twelfth dorsal vertebræ in a laborer, nineteen years of age. The cord was almost completely gone, there being a few fibers remaining from its anterior portion. The laminæ had been fractured and driven into the canal. One of the articular processes had also been driven into the canal. These were removed, and the wound closed, leaving a small catgut drain. There was no decided improvement in his condition for six weeks after the operation. At this time he urinated voluntarily.

Two weeks later there was noticeable improvement in both sensation and motion in the thighs. This improvement continued until the present, about three years after operation. His thighs were practically normal as to motion and sensation. Bladder and rectum acted naturally, and his general health was excellent. He could stand with support and walk by having a strong support on each side. His legs and feet were still paralyzed both as to motion and sensation. At present the patient weighed nearly two hundred pounds and was quite comfortable, except for occasional pains in his legs.

NEOPLASMS, WHEREVER SITUATED, SHOULD, IF POSSIBLE, BE REMOVED, WHATEVER THEIR APPARENT NATURE.

Dr. Maurice H. Richardson, Boston, Mass., considered chiefly neoplasms of the breast and of the female pelvis in a paper on this subject. The reasons which justified the adoption of the title rule in these regions would apply with certain exceptions to all parts of the body. These reasons, all of which were illustrated by specific cases, in the author's own experience, were as follows:

(1) The uncertainty of the diagnosis, even on the part of the most experienced and the most skillful, made palliative treatment hazardous, especially in the doubtful cases. Several instances were given in which the patient was not operated upon because the tumor was supposed to be benign when, in reality, it was malignant. The error cost the patient the favorable moment for operation. The impossibility of accurate diagnosis in even the most accessible regions of the body was emphasized. Breast tumors apparently benign had proved malignant. Breast tumors benign throughout their principal area showed minute foci of malignancy. Breast tumors clearly benign had after many years developed a fatal malignancy. So in abdominal tumors, especially the pelvic tumors in women, the difficulties of diagnosis made the apparently benign cases dangerous. Many instances were given illustrating the difficulties of diagnosis and the necessity for exploration in even the most favorable cases of presumably benign growths.

(2) The dangers of benign tumors becoming in time malignant was emphasized and illustrated by not a few cases in which after years of slow and harmless growth a tumor had suddenly developed evidences of malignancy. Tumors of the breast, of the gall-bladder, the stomach, the uterus, the ovary, and of other regions had by an acquired malignancy convinced the speaker that the only safe rule of treatment was in all cases thorough extirpation of the tumor as early as possible.

(3) The wisdom of exploration in certain apparently hopeless tumors was illustrated by cases in which a benign and easily remediable condition was found, and in which impending death was averted by a safe operation. In this class were infiltrating tumors of the abdominal wall supposed to be hopelessly malignant, but which proved to be tuberculosis of the muscle aponeurosis; epigastric tumors, apparently cancerous, found to be pancreatic cysts, actinomycosis, chronic pancreatis and the like; pelvic tumors supposed to be malignant and inoperable were proved to be old tubal inflammations, fibroids, ovarian cysts, and the like.

(4) The essential malignancy of certain areas in the malignancy-inviting nature of certain regions, especially the breast and the ovaries, was especially emphasized. In these regions the tendency of tumors to become malignant made the application of this rule practically imperative. Ovarian tumors, even when apparently benign, were shown to have especially dangerous tendencies to malignant degeneration.

(5) In pelvic tumors especially, the benign often masked the malignant. Cases were reported to illustrate the obscuration of a uterine sarcoma by an overlying fibroid. In two recent cases cancer of the ovary was found concealed by an enormous fibroid, and in a third there was found an annular stricture of the sigmoid flexure.

The rule of universal extirpation had numerous exceptions. It should not apply to superficial tumors, clearly benign, which could not be removed without great disfigurement; keloids that could not be removed without leaving a broad scar, unless they showed a tendency to ulceration and malignancy; all other benign tumors, which caused needless suffering, disability and disfigurement, whenever their removal was dangerous, or whenever the patient's general condition was unfavorable; and tumors of all kinds in which the dangers and sufferings of removal outweighed the dangers and sufferings of the tumors themselves.

INTESTINAL CANCER.

Dr. J. Garland Sherrill, Louisville, Ky., stated that cancer of the intestine, while rare, was more frequent than physicians were led to believe; that sarcoma was much less frequent than carcinoma, and selected especially the small intestine, while carcinoma most often attacked the large bowel. The appendix was the seat of both carcinoma and sarcoma, although occurring quite infrequently. The literature showed that men suffered from both forms oftener than women. Adeno-carcinoma was the type most frequently seen, while the round-celled sarcoma or the lymphosarcoma occurred oftenest.

The author reported two cases of cancer of the intestine. The treatment was to be largely determined by the extent of the involvement. Resection of the intestine and extirpation of the growth offered the patient the only hope of a permanent cure, and this chance, though slight, should be given the patient whenever parcticable, as early in the course of the disease as possible. Any of the classic methods might be employed.

AMPUTATION OF THE HIP JOINT FOR SARCOMA, WITH A REPORT OF SEVEN CASES.

In a paper on this subject, Dr. Wm. B. Coley, New York, said that the tumor originated in the bone or periosteum of the femur in five cases, and in the soft parts in two. The age of the patients ranged between six and fifty-six years. In six cases Wyeth's pins were used, but in the seventh case the growth extended above Poupart's ligament; pins could not be used, and the external iliac artery was first tied. All of the patients made a good recovery from the operation; yet only one patient survived operation long enough to be called a cure. This was a

sarcoma of the thigh in which the mixed toxins of erysipelas and Bacillus prodigiosus were used for two months before amputation. In one recent case the patient was still alive without recurrence; in all the other cases death occurred from local or general recurrence in from four months to two years after amputation. Of four other cases of sarcoma of the femur and thigh, treated by high amputation just below the trochanter, two patients died at the end of four months; one died at the end of two and a quarter years, and a third had recurrence in the gluteal region, which disappeared under the mixed toxin treatment, and the patient was alive at present without recurrence, six years afterwards.

The extraordinary malignancy of sarcoma of the femur was shown by the very small number of patients known to have survived for more than three years after the amputation. Butlin was able to find but one case in sixty-eight treated by high amputation or hip joint amputation. Wyeth, in 1901, collected 131 cases treated by hip joint amputation with ten alive more than three years. Dr. Coley stated that he had personally known of but six cases. In one of these cases (Dr. Bull's), operated upon sixteen years ago, a severe infection occurred in the wound, probably streptococcus, and the patient was well six years later. In another case (Dr. Gerster's), the disease was so extensive and so high up that amputation was considered impossible, and the patient was treated with the mixed toxins of erysipelas and Bacillus prodigiosus for several months. The tumor disappeared and the patient was shown to the New York Surgical Society a year ago in perfect health, more than four years after treatment.

The better results following amputation in the pre-antiseptic days the writer attributed to the infection that frequently occurred in the earlier period. This fact, together with the results referred to, in which the erysipelas toxins were used, he believed sufficient reasons for advocating the systematic use of the toxins after primary amputation as a prophylactic against recurrence. He would not advise such treatment prior to amputation in sarcoma of the femur, on account of the great liability to early metastases, although in a case of sarcoma of the tibia he had been able to save the leg, and the patient was now well seven years afterwards.

The method of treatment advocated by Mikuliez, namely, resection of the femur, Coley did not think should be adopted as a substitute for amputation. While it was true a fairly useful limb might be obtained by resection, there were no cases treated by this method that had been observed for longer than a year, hence nothing could be said as to permanent cure.

The x-ray, Coley believed, should never be used unless the patient absolutely refused amputation. One such case he had treated two years ago (round-celled sarcoma of femur); the tumor apparently entirely disappeared from the femur, but ten months later a large metastatic tumor appeared by operation. A little later another very large tumor appeared in the lumbar and iliac regions. Under long-continued treatment with the mixed toxins plus the x-ray, the tumors disappeared, and the patient was alive and well to-day, although by no means regarded as cured.

DIAGNOSIS AND TREATMENT OF GALL STONES.

DR. MACK ROGERS, Birmingham, Ala., read a paper on this sbuject. After referring to the differential diagnosis, he spoke of the operation for the removal of stones from the gall bladder, saying that where there were no adhesions it was comparatively easy, but when the stone was located in the common duct, or extensive adhesions existed, or both, the surgeon had a very difficult condition to deal with. The mortality in all cases from the operation averaged only about 3%.

SURGERY OF URINARY TUBERCULOSIS IN WOMEN.

DR. GUY L. HUNNER, Baltimore, Md., reported thirty-five cases occurring in the services of Dr. Howard A. Kelly and his associates in Baltimore. These patients were all women with an average age at the onset of symptoms of twenty-eight years. The disease was unilateral in thirty-one of the cases, and it was probably primary in the kidney, as regards the urinary system, in thirty or more of the cases. Thirty-one cases had bladder symptoms at some time in the course of the disease, although only eighteen cases had bladder lesions at the time of operation. Eleven of these eighteen cases still had some bladder symptoms, and five were known to have bladder lesions, although nine of the eleven had had systematic bladder treatment. Tuberculosis of the bladder did not heal with the ordinary methods of treatment, and if the disease persisted a year and did not occupy more than half of the bladder, it should be excised. Of twenty-two ureters examined microscopically, seventeen showed tuberculosis, while five were chronically inflamed. If a tuberculous ureter remained either in part or *in toto*, the wound usually remained open at least two years, while the removal of a ureter with the kidney resulted in rapid closure of the wounds. Five cases died — three after six and eleven weeks and two years respectively, from involvement of the other kidney, and two, in fifteen and six days, because of the operation. Sixty-six per cent of the patients were enjoying fairly good or excellent health.

(To be continued.)

RADIUM IN AN ITALIAN RIVER. — Dr. Francolini of Rome, Italy, has published a statement to the effect that the source of the Clitumnus, a small Umbrian river sacred to the Romans, may contain radium, basing his opinion on a description by Pliny and on passages in the works of many writers and poets from Virgil to Byron. — *N. Y. Medical Journal.*

Recent Literature.

Rational Home Gymnastics. For the "Well" and the "Sick," with Health-points on Walking and Bicycling, and the use of Water and Massage. By HARTVIG NISSEN. With illustrations of Exercises for Women contributed by BARONESS ROSE POSSE. Revised and enlarged edition. Boston: E. H. Bacon & Co. 1903.

This small volume of 132 pages is devoted to a discussion of rational home gymnastics. The illustrations are so numerous that the various movements suggested are graphically represented in practically every instance. Baroness Rose Posse gives in addition a series of illustrations of exercises for women which should be of service in indicating proper methods. The book is suggestive and should be useful as a guide for those undertaking gymnastic exercises of this type without an instructor.

A Treatise on Diseases of the Rectum, Anus, and Sigmoid Flexure. By JOSEPH M. MATHEWS, M.D., L.L.D., President of the American Medical Association, 1898; Professor of Surgery and Clinical Lecturer on Rectal Diseases at the Hospital College of Medicine, etc. Third edition, revised. New York: D. Appleton & Co. 1903.

The author has devoted many years to the study and teaching of rectal diseases. The amount of original work which has been done in this subject as well as the fact that the second edition was exhausted has induced Dr. Mathews to produce a third one. This new volume of 589 pages presents the subject generally and specifically. The introductory chapters describe the methods of examination of patients, the anatomy of the rectum, special instruments of diagnosis, constipation, anesthesia and rectal antiseptics. The remainder of the book treats of hemorrhoids, fistulæ, ulceration, non-malignant stricture, carcinoma (under which both the operative and the palliative treatment is discussed), diseases of the "Sigmoid," prolapse, malformations, polypi, etc. The book is illustrated with six chromo-lithographs, rather lurid in character, and numerous cuts.

Much has been added to the earlier editions which is new and of importance to those interested for any reason in rectal diseases. The chapter on "Cancer" has been rewritten to bring the subject up to date and introduce the more recent ideas relating to etiology. The author calls attention to several operations of which he claims to be the originator, *viz.:* A method of colopexy for extreme cases of rectal prolapse; a new operation for hemorrhoids which might be termed an excision; a plastic operation for pruritus ani. Also an operation for rectal prolapse of moderate degree.

The book is a "readable" one, with clear type and pages agreeably free from the luster of a highly finished calendar paper. It is forcibly and positively written. The subject matter, both etiology, diagnosis and treatment, is often emphasized by illustrative clinical histories of actual cases which have come under the author's personal observation. He also often quotes in support of his statements, or to present the prevailing ideas on the subject under discussion, the opinions of other specialists, notably Allingham, Cripps, Tuttle, Kelly, Agnew and Kelsey; so that one feels after reading that a fairly comprehensive view of the subject has been obtained. The book contains many practical suggestions and details of treatment which are of value. It impresses one that its author is thoroughly convinced that his statements are supported by facts which will bear the test of actual trial by others.

Surgery, Its Theory and Practice. By WILLIAM JOHNSON WALSHAM, F.R.C.S. Eng.; M.B. and C.M., Aberd.; Surgeon, formerly Lecturer on Surgery and Anatomy, St. Bartholomew's Hospital; Member of the Court of Examiners, Royal College of Surgeons of England; Consulting Surgeon to the Metropolitan Hospital, to the Hospital for Hip Disease, Sevenoaks, and to the Cottage Hospital, Bromley; Late Surgeon in Charge of the Orthopedic Department, St. Bartholomew's Hospital; Examiner in Anatomy to the Conjoint Board of the Royal College of Physicians and Royal College of Surgeons, and University of Aberdeen; and Examiner in Surgery to the Society of Apothecaries. Eighth edition. With 622 illustrations, including 20 skiagram plates by WALTER GEORGE SPENCER, M.S., M.B. (Lond.); F.R.C.S. Eng.; Surgeon to the Westminster Hospital. Philadelphia: P. Blakiston's Son & Co. 1903.

Thirty-eight thousand copies of this book have been published and in this eighth edition Mr. Walsham was aided by Mr. Walter G. Spencer. The book is so well known that an extended review is hardly necessary. Some of the illustrations are rather antiquated. The book shows evidence of a great deal of care having been taken to bring it thoroughly abreast with the times. The book may well be accepted as a representative text-book of English surgery.

Modern Bullet Wounds and Modern Treatment, with Special Regard to Long Bones and Joints, Field Appliances and First Aid. By MAJ. F. SMITH, D.S.O., Royal Army Medical Corps. London: J. and A. Churchill. Philadelphia: P. Blakiston's Son & Co. 1903.

This little volume of 99 pages is a reprint of part of the essay to which was awarded the Alexander prize for 1903; a prize awarded triennally from a fund instituted to perpetuate the memory of Thomas Alexander, C.B., the Director-General of the British Army Medical Corps from 1858–1860.

The brochure treats of the injuries of the large bones of the upper and lower extremities, and the

joints with which these bones are associated. The opinions of the author are based on his experience, derived from the Boer war and other campaigns. Wounds by older firearms are compared with those resulting from projectiles from modern weapons. The injuries are grouped into: (1) Contusions with injury to the periosteum without fracture. (2) Partial fracture without much impairment of function. (3) Complete fracture. (4) Comminuted fracture. (5) Any of the above involving a joint. (6) Injury to joints without injury to bones. These different lesions are described and discussed. The results of previous campaigns, where different weapons and methods of treatment were used, are compared with present methods and results. Major Smith enumerates his reasons for these improved statistics by modern methods of treatment. This discussion occupies a greater part of the book. The points are interestingly presented and the author's opinions are frequently emphasized by quotations of personal observations. Many practical points of diagnosis and treatment the value of which has been actually and personally tested are incidentally introduced.

The concluding pages are devoted to the consideration of splints for actual field service (a subject very briefly presented) and a short discussion of the management of " First Aid " on the " firing line."

The book impresses one as the work of a man who has formulated his ideas from personal observation, and it makes interesting reading when compared with the more theoretical and elaborate treatises on military surgery.

Essentials of Pelvic Diagnosis, with Illustrative Cases. By E. STANMORE BISHOP, F.R.C.S. Eng.; Hon. Surg. Ancoats Hospital, Manchester; Vice-President British Gynecological Society, London; Ex-President Clinical Society, Manchester, etc.; and an Appendix on Examination of Blood, etc., by CHARLES H. MELLAND, M.D. (Lond.), M.R.C.P., Hon. Physician, Ancoats Hospital, Manchester, etc. New York: William Wood & Co. 1903.

This is a volume of 297 pages, attractively published by William Wood & Co. The author adopts the deductive method of teaching diagnosis. As he puts it, " Procedure on the inductive principle is the very reverse to that upon which all men in practice are called upon to act. In practice, the symptoms are known, the disease is not. It has to be deduced; and this work is an attempt to make this mental process with regard to pelvic diseases more easy."

The treatment of the subject is best outlined by the Table of Contents. Part I is headed " Methods of Diagnosis," and contains chapters on The Use of the Hand; The Position of Patients for Purposes of Diagnosis; The Use of Instruments for Diagnosis; and Pain as a Factor in the Diagnosis of Abdomino-Pelvic Disease.

Part II is called " Lines of Diagnosis," and the chapters are as follows; Class I: Swellings of the Abdominal Wall Itself. Class II: Conditions affecting Perineum, External Genitals, and Inguinal Region. Class III: Diseases affecting the Vagina, Rectum, Bladder and Prostate, diagnosable by Touch, Specula, Cysto- and Proctoscopes. Class IV: Swellings in the Pelvis, felt bimanually. Class V: Swellings of Pelvic Origin, which have developed into the Abdomen.

Part III is devoted to Diagnostic Tables; Part IV to Illustrative Cases, and Part V is the Appendix containing the Examination of the Blood and Examination for Tubercle Bacilli and Gonococci, and also, the Index, which is of especial value to the practitioner who happens to have been trained by the inductive method, or to the student who has a suspicion as to the identity of the disease he is seeking.

It would seem as if the author had distorted the symptomatology of some of the diseases of the pelvis in order to make them fit into his tables, unimportant symptoms being given undue prominence and important ones placed in the background or omitted. Nevertheless, the book has a distinct value for the elementary student, founded as it is on an ample clinical experience and written in a clear, forcible style. For the advanced student and the practitioner, to our mind, the inductive method of teaching is to be preferred as affording a much clearer and more accurate picture of each disease.

Adenomyome des Uterus. VON THOMAS S. CULLEN, Hülfsprofessor der Gynäkologie an der Johns Hopkins Universität, Gynäkologischer Assistent am Johns Hopkins Hospital in Baltimore, U. S. A. Mit 45 Abbildungen im text. Berlin: Verlag von August Hirschwald. 1903.

This book of 91 pages is an article written by Dr. Cullen for the festschrift in honor of Prof. Johannes Orth to celebrate the twenty-fifth year of his professorship.

Adenomyoma is treated in detail. It is a distinct pathological condition which may be diagnosed both by gross appearances and by the microscope. It is non-malignant and does not return when removed. Adenocarcinoma may be engrafted on adenomyoma or may exist independently in the same uterus.

Dr. Cullen distinguishes three types:

(1) Adenomyoma with little change in the normal shape of the uterus.

(2) Subperitoneal or intraligamentary adenomyoma.

(3) Submucous adenomyoma.

The etiology, diagnosis, prognosis and treatment of adenomyoma and its relation to adenocarcinoma are carefully discussed. Cases of adenomyoma of the bones, of the uterus and of the round ligaments are reported.

The article is well illustrated by numerous cuts and is a valuable addition to our knowledge of the diseases of the uterus.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JANUARY 21, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal. 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

THE FINANCIAL PROBLEM OF THE NEW YORK HOSPITALS.

ATTENTION is called, in the current number of *Charities*, to the financial problem connected with the adequate maintenance of the hospitals in New York. One hardly realizes the extraordinary change which has taken place in such institutions during the past fifty years, unless attention be called to the matter. The growth and development of hospitals has been particularly active in the immediate past, and further inlargements and improvements, which are projected, will entail an added expenditure of between six and seven million dollars. More than half a million dollars has recently been expended for the further equipment of hospitals under the jurisdiction of the department of public charities.

With the increasing knowledge of methods of caring for the sick, together with the elaborateness of new hospital buildings, it has happened that the cost of maintenance has been very materially increased. The prejudice against hospitals has practically disappeared, and this fact, together with the very great difficulty of treating patients by modern methods at their homes, has necessitated this remarkable growth of hospital facilities. This has meant an increasing financial strain, so that the situation has now reached a critical point. A table, showing the financial burden which is being carried by twenty hospitals, is appended, giving an annual deficit of $432,268. Of this amount one hospital, the Lying-in, alone carries upwards of $88,000, and the Presbyterian is very near that figure. This deficit of nearly $450,000 has accumulated in the short space of one year, and that a year of great financial prosperity.

Various methods must be adopted to meet this deficit, one of the most important of which undoubtedly is by taking such portions of accumulated endowment funds as are not restricted, but which heretofore have been kept for income-producing purposes alone. Legacies to hospitals are too uncertain to permit of dependence. The natural question arises as to how the receipts of the hospital may be increased.

At present the income of hospitals comes from paying patients, from endowments, legacies, donations, and an allotment from the Hospital Saturday and Sunday Association, with a certain allowance from the city in some cases. It is undoubtedly true that in certain institutions there are increased receipts from pay patients, but this does not necessarily help those who can afford to pay little or nothing. Income from endowments is, in many cases, decreasing, and legacies are too uncertain to count upon. Donations again are not a hopeful source of increase in income. The conclusion, therefore, is reached that the deficit must be met by other means than these. With the very great added expense which the city is undertaking for the betterment of its own hospitals, it is not likely that it will view with approbation a suggestion to increase the amount it is now paying to private institutions.

It may be seen from the foregoing that the situation is not encouraging. There is a marked tendency toward the building and equipment of hospitals, which, under present conditions, must be maintained at a constant loss. *Charities*, in the paper by Frank Tucker to which we are referring, takes the bull by the horns and suggests that an endowment fund of ten million dollars be raised for the hospitals of New York. The income of this amount is required to provide for the present annual deficit. The method of raising such a fund must be through the work of an independent body of representative citizens, and when raised it should be held only for purposes of income. This suggestion strikes one at first as somewhat bold, but the cause is a good one, and if persons of wealth are made to realize this fact, experience amply shows that they are quite willing to give. However this may be, it is apparent that some remedy must be sought if hospitals are to go on developing in proportion to the need and growth of the population. There are those who believe that a limit should be set to the foundation of hospitals on an essentially

charitable basis, among whom may be mentioned Bishop Potter, of New York, who regards the growth of institutionalism as a possible menace. The weight of opinion will, however, no doubt be in favor of a conservative but continually increasing development of hospitals and hospital facilities, recognizing the possibility and the danger of overproduction in this as in other matters. In the meantime existing hospitals should be adequately supported, and we can see no objection to the proposition which is set forth in *Charities* of securing, if possible, an endowment fund for this purpose.

ADULTERATION AND SUBSTITUTION.

IN an official report to the State Board of Pharmacy, made by Dr. George C. Dickman of the New York College of Pharmacy, who is chairman of the board's Committee on Adulteration and Substitution, it is stated that examinations during the past year show that one out of every three druggists in New York City and its vicinity is guilty of dispensing medicines below the official standard. Inspectors, under Dr. Dickman's orders, went from shop to shop buying samples of such staple preparations as tincture of iodine, spirit of camphor and soap liniment. The results tabulated are as follows: Samples tested, 871; up to standard, 561; below standard, 310; per cent, 35.5. No attempt was made to pick out suspected druggists, the samples being purchased at random. Tincture of iodine was found in which not one-quarter of the prescribed quantity of iodine was dissolved. The use of wood alcohol was found to prevail to a large extent in the preparation of certain tinctures. Of 489 samples of tincture of iodine, spirit of camphor and soap liniment, wood alcohol was substituted in 94. During the first half of the year this adulteration was found in 23% of the samples tested, but in the last six months, during which it is stated the drug-trade journals reported from time to time that samples were being collected, the percentage fell to 16%. The State Board divides the state into three districts, of which the Greater New York district includes Westchester County and Long Island. In the two other districts the board's inspectors visited only druggists under suspicion, and in the middle district, which includes the cities of Albany, Syracuse and Rochester, all but ten out of ninety-eight samples collected were bad. In the western district, in which Buffalo is the only large city, but seven samples were tested, but they were all bad. In the New York district more than $20,000 in fines was collected without resort to the courts, the method being to inform the dishonest druggist that he had been detected and that his fine is so much; whereupon he promptly sends in a cheque for the required amount.

The United States Supreme Court has also rendered a decision sustaining the New York statute relating to the adulteration of food products. The case was that of a firm of New York importers *vs.* a merchant who made a contract to purchase coffee of a prescribed grade at a specified price. When the coffee arrived in New York it was discovered to have been colored. The merchant raised the point that the coloring process was equivalent to adulteration, and the New York courts sustained the contention, and relieved him from the requirements of the contract. The attack on the state law was made on the ground that it was an assumption of powers belonging to the United States as governing inter-state commerce. The Supreme Court held that the adulteration of the coffee was an act which came clearly within the police powers of the state as a matter of public welfare within the state. No matter where the adulteration was made, when the resulting product was brought into the state, it was subject to the laws of the state, precisely as if the adulteration had been an act committed within the borders of the state. To hold any other position in a matter relating to the health of the people of the state would be to hold that the state had no power to protect itself against all manner of assaults on public health and welfare.

MEDICAL NOTES.

PENNSYLVANIA SOCIETY FOR THE PREVENTION OF TUBERCULOSIS. — The annual report of the Pennsylvania Society for the Prevention of Tuberculosis shows the same sort of activity in combating the disease there as in other states. Six tracts are published in this pamphlet on the general subjects of how to avoid contracting tuberculosis; on how the transmission of the disease may be avoided; how hotel keepers may aid in preventing the spread of the disease; how storekeepers and manufacturers can assist to prevent the spread of the disease; and finally the registration of tuberculosis. These tracts are published by the society for gratuitous distribution.

INSANITY AMONG INDIANS. — It is reported from the National Hospital for Insane Indians in South Dakota that the institution now has thirty-four patients, and that it will soon be filled at the present rate of increase. Mental disorder is increasing among reservation Indians, supposedly due to the semi-civilized life which is being forced upon them.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Jan. 20, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 81, scarlatina 44, typhoid fever 8, measles 146, smallpox 0.

MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Jan. 16, was 236, against 202 the corresponding week last year, showing an increase of 34 and making the death rate for the week 20.39. Of this number 114 were males and 122 were females, 228 were white and 8 colored, 146 were born in the United States, 87 in foreign countries and 3 unknown, 55 were of American parentage, 147 of foreign parentage and 34 unknown.

The number of children who died under one year was 44, against 31 in 1903; the number under five years 76, against 50 in 1903. The number of persons who died over sixty years of age was 44. The deaths in public institutions were 63. There were 13 deaths from Bright's disease, as against 8 during the corresponding week of 1903. There were 11 deaths from cancer. In the same week of 1903 there were but 5.

MEETING OF MASSACHUSETTS NURSES. — At a recent meeting of the newly organized Massachusetts State Nurses Association, held in Boston, a large number of nurses were in attendance. The membership in the Association is now about 300, and it is confidently expected that it will fulfill the function for which it was organized.

THE BOSTON DISPENSARY. — At the quarterly meeting of the Boston Dispensary certain statistics of interest were presented. The work of the Dispensary during the quarter is represented by the treatment of 6,936 patients at the Dispensary and 2,282 visits to new and old patients. Upwards of 6,000 visits were made in the various districts, and the total number of patients treated by the institution numbered over 10,000. Attention was again drawn to the necessity for more room in order properly to carry on the work of the Dispensary. Since the last report a new district has been established in Charlestown.

MASSACHUSETTS HOSPITAL FOR DIPSOMANIACS AND INEBRIATES. — The twelfth annual report of the trustees of this institution shows that the policy introduced the previous year of selecting cases more carefully for treatment has led to a certain diminution in numbers. The appearance of smallpox, which, however, gained no headway, also conduced to this result. Certain improvements have been made during the year, and further means have been taken for preventing escape. The largest number of patients under treatment during the year was 182, the smallest 105, a very considerable decrease over the preceding year. The superintendent in his report is strongly convinced of the benefit which has resulted in a very large percentage of the cases treated. Of all who have received the full course of treatment, 42% during the ten years of the existence of the hospital have been either cured or improved.

MEDICAL USES OF RADIUM. — In the course of an address on Jan. 13, before the Technology Club, Boston, on the medical uses of radium, Dr. William J. Morton made the suggestion that the efficacy of certain natural mineral waters may possibly be due to the presence in them of minute quantities of radium or its emanations. It seemed probable, he said, that these spring waters contain something that till now has escaped the tests of the analyst, and the known fact that some of the potent waters have radioactivity of one kind or another would seem to point to the presence of radium or the related substances.

NEW YORK.

PNEUMONIA AND THE DEATH RATE. — During the week ending Jan. 9 there were 364 deaths reported from pneumonia (including cases of broncho-pneumonia), an increase of 143 as compared with the corresponding week of last year, and the mortality in the city from all causes represented an annual death rate of 22.23, as against 18.45 in the corresponding week of 1903.

A CENTENARIAN. — Mrs. Susan Jane Weeks died recently in the Williamsburgh district of Brooklyn at the age of one hundred and two years. She was born in Babylon, Suffolk County, N. Y., and was a descendant of an old Dutch family which settled on the east end of Long Island in the early part of the seventeenth century.

HERTER LECTURESHIP. — In the lectureship established at the University and Bellevue Hospital Medical College by Dr. Christian A. Herter, the first series of twelve lectures has just been delivered by Dr. W. D. Halliburton, Professor of Physiology at King's College, London, and Croonian Lecturer before the Royal College of Physicians in 1902. The lectures, which were given daily at the Carnegie Laboratory, were devoted to the bio-chemistry of muscle and nerve.

CONSULTING SANITARIAN TO BOARD OF HEALTH. — Ex-Commissioner Ernest J. Lederle has been appointed consulting sanitarian to the Board of Health, and in this capacity will also sit as a member of the Advisory Board of the Department, which has hitherto been composed entirely of physicians. Prof. Charles F. Chandler, another ex-president of the department, has likewise been appointed a member of the Advisory Board.

Miscellany.

THE DEVIATE.

THE following verses, which have a bearing on the general subject of "Degeneracy and Deviation," were read by Mr. William A. Hovey at a meeting of the Boston Society of Psychiatry and Neurology, in connection with the paper by Dr. George L. Walton on this subject, published in this issue of the JOURNAL:

THIS deviation is a thing
Heredity alone can bring,
It sort of means you went astray
Before you saw the light of day.
It doesn't come because you've sought to
Do things that you hadn't ought to.
It don't arise from frequent "wets,"
Nor even smoking cigarettes.
It comes because you're built that way
And when it comes, it comes to stay.

It isn't nice, at any rate
To call your friend "degenerate"
Because his hands are large or small,
Because in height he's short or tall,
Because his eyes, one brown, one blue,
To normal standards are not true.
And if he be much bigger, stronger,
With every chance of living longer,
Than any man you've seen or known,
A man with powers all his own,
You may call him a "deviate"
But surely not "degenerate."

I know a man of strenuous mold
Of stalwart build, of aspect bold,
Of reddish hair, of mild blue eye
And with a very potent thigh—
A man who's built for boxing, rowing,
Who's ever to the river going
To find a vent for his great store
Of vital force. He has galore
Of brawn and muscle, blood and bone,
I think he weighs some fourteen stone.
His blood goes racing through his veins
Like mile-a-minute railroad trains,
And keeps on building brain and muscles,
Because its full of red corpuscles.
Now if you'd keep away from harm
Fight very shy of that right arm
And never, never seek to know
The fearsome twist of that elbow.
This man, to speak in parlance formal,
Is most distinctly supernormal
But, to his face, I think you'd hate
To call him a "degenerate."
You'd safely say an "aberrate,"
An "abnorm" or a "variate,"
But Walton's word is "deviate."

Another man I have in mind,
He's of a very different kind,
He's neither very short nor tall,
But he is one who "knows it all."
His brain is of the average size,
He doesn't differ as to eyes,
From other men who chin and chatter,
The kind whose talk is mainly clatter.
He went through college, that of course;
And yet, if you should own a horse
E'en half as stupid as is he
You'd shoot him, sure as sure can be,
For none of us can really need
A critter that can't earn his feed.
He'll tell you all his blood is blue
And I'm inclined to think it's true,
For of good blood it's often said
"Damn the color, so it's red."
He never smokes, he rarely drinks,
He's one of those who thinks he thinks;
In fact he's just a deviate.
'Twas written in the book of fate
There was a twist in his creation
And he's a case of deviation.
And so you see it's come to pass,
That he's a solemn, pompous ass.
He's very proud, he's fat and sleek
And thinks God kissed him on the cheek
He can't get out this spell from under,
If you can cure him, you're a wonder.

Another man I have in mind
A doctor of the country kind.
He practices among the lowly
And criminals, and men unholy,
Quite frequently his talk reverts
To curious cranks and queer perverts.
And, nothing strange, he holds the view,
And some of you may hold it too,
That too much smoking, too much drinking
And toxic drugs of which I'm thinking
Will make men take to dreadful things
Whose very names would make you cringe.
No doubt he's right. But these he'll rate
As men who are degenerate.
In other words, he'll say to you,
And this is quite a common view,
That when you say "degeneration"
You mean a moral degradation.
Now that's not what you mean to say
And yet, there is the deuce to pay

If you call one "degenerate"
Who really is a "deviate."

So now I think you'd better plan
To just construct an average man.
And if one differ, foot to crown
From these fast lines that you lay down,
Whether for better or for worse,
The small details I can't rehearse,
Just give a try to Walton's plan
And say that he's a devious man,
Who may not be "degenerate"
But all the same, a "deviate."

TREATMENT OF EPILEPSY BY ROENTGEN RAYS.

AT the annual meeting of the Medical Association of the Greater City of New York, Dr. J. H. Branth read a paper in which he reported encouraging results in the treatment of epilepsy by means of the Roentgen rays. He stated that in many instances the occurrence of the seizures was believed to depend upon the instability of the cellular brain elements, or an abnormal metabolism, and as it was accepted by many authorities that the x-ray stimulates the vital activity of protoplasm, it was upon this theory that the treatment was adopted. Naturally, he said, all cases of epilepsy are not amenable to it, as, for instance, those in which decided degenerative processes in the brain have set in. By radiographs taken by himself Dr. Branth demonstrated that part of the x-rays unquestionably pass through the skull, and he regarded it as fair to assume that more than twice the quantity pass through the middle of the brain, as in light the power diminishes by the square of the distance. In his cases three treatments per week are given, beginning with five minutes' exposure at fifteen inches' distance, and gradually extending this to ten minutes' exposure and ten inches' distance. A hard, or high vacuum tube is employed, and a different part of the skull is exposed at each sitting. In both *grand* and *petite mal* it has been observed that the seizures became lighter and of shorter duration, that the intervals became longer, and that if an attack occurred, it was followed by less prostration. In patients with six to eight seizures a day, after the treatment had been taken for a few weeks, intervals of two and three weeks were noted. The hair may drop out in areas, but it is certain to return in a stronger growth than before. In a few instances, where the patients appeared to have acquired a bromide drug habit, the best results were obtained by continuing small doses of bromides, in addition to the x-ray treatment. With few exceptions the patients gain in weight at an impressing rate. A remarkably successful case was presented, that of a lad fourteen years of age who had not had a single seizure since the treatment was commenced, on Nov. 8, and who had astonished his family and teachers by the extraordinary improvement he had made both mentally and physically.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JAN. 9, 1904.

CITIES.	Population Estimated, 1904.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Acute lung diseases.	Diphtheria and croup.	Diarrheal Diseases.	Typhoid fever.

Deaths reported, 3,387; under five years of age, 911; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 644, acute lung diseases 776, consumption 320, scarlet fever 49, whooping cough 4, cerebrospinal meningitis 12, smallpox 4, erysipelas 13, puerperal fever 17, measles 20, typhoid fever 40, diarrheal diseases 60, diphtheria and croup 102.

From whooping cough, New York, Baltimore, Pittsburg and Boston, 1 each. From smallpox, Pittsburg 4. From cerebrospinal meningitis, New York 5, Baltimore, Boston, Cambridge, Somerville, Brockton, Marlborough and Gardner, 1 each. From erysipelas, New York 6, Chicago 4, Pittsburg, Boston and Worcester, 1 each.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Dec. 26, the death-rate was 15.4. Deaths reported, 4,464; acute diseases of the respiratory organs (London) 139, whooping cough 111, diphtheria 38, measles 130, smallpox 5, scarlet fever 25.

The death-rate ranged from 7.1 in Barrow-in-Farnace to 29.4 in Wigan; London 13.6, West Ham 11.7, Brighton 12.1, Southampton 10.9, Plymouth 18.2, Bristol 16.2, Birmingham 16.9, Leicester 12.8, Nottingham 12.5, Liverpool 20.7, Bolton 15.9, Manchester 19.6, Salford 15.2, Bradford 21.5, Leeds 20.3, Hull 14.6, Cardiff 12.4, Rhondda 16.6, Kings Norton 10.6, Preston 24.6.

METEOROLOGICAL RECORD.

For the week ending Jan. 9, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING JAN. 16, 1904.

CRANDALL, R. P., surgeon. Detached from the Naval Station, Guam, L. I., and ordered to the Wisconsin.

MURPHY, J. A., P. A. surgeon. Commissioned a P. A. surgeon from March 3, 1903.

HEINER, R. G., and STOOPS, R. E., doctors. Appointed assistant surgeons with the rank of lieutenant (junior grade), from December 26, 1903.

SOCIETY NOTICES.

ANNUAL MEETING EASTERN SECTION AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY. — The Eastern Section of the American Laryngological, Rhinological and Otological Society will hold its annual meeting at the Young Men's Christian Association Building, Corner North Main and Pine Streets, Fall River, Mass., Saturday, Jan. 30, 1904, at 2.30 P.M. The medical profession is cordially invited to attend the meeting.

WENDELL C. PHILLIPS, M.D., Secretary.

MEDICAL SOCIETY OF THE STATE OF NEW YORK. — The 98th Annual Meeting of the Society will be held January 26, 27 and 28, 1904, in the City Hall, Albany, commencing at 9.30 A. M. on the 26th, and ending at 1 P. M. on the 28th.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR SURGERY. — A meeting of this section will be held at the Medical Library, on Wednesday evening, Feb. 3, at 8.15 o'clock. The subject for discussion will be: "The Technique of Gastroenterostomy." The first half of the meeting will be taken up by the presentation of eight five-minute papers or demonstrations of special details of this operation. Members who cannot attend the meeting are requested to send to the Secretary brief reports of any cases (particularly the unsuccessful ones), illustrating special points of interest in relation to this subject.

E. A. CODMAN,
Secretary.

104 Mt. Vernon Street.

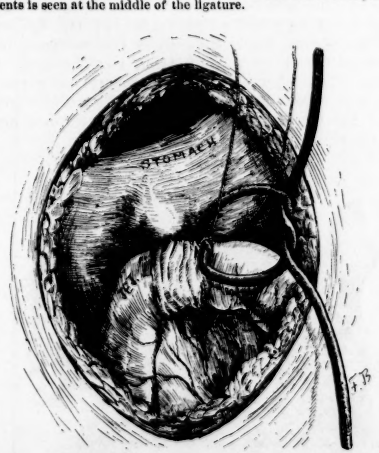
EXPERIMENTS WITH THE McGRAW ELASTIC LIGATURE.*

BY FRED T. MURPHY, M.D., BOSTON.

From the Surgical Laboratory of the Harvard Medical School.

Gastro-enterostomy and lateral anastomosis have come to occupy so conspicuous a position in the field of abdominal surgery that any procedure which will decrease the operative risk is of the greatest importance. Mechanical devices almost without number have been introduced to assist in perfecting the technic of the operation, but one by one they have been discarded. Operators generally have gone back to the simple suture. The suture possesses the advantage of universal adaptation to all conditions and in the hand of the expert the difficulties attendant upon its use — time necessary for application, failure to obtain solid joints and the danger of soiling the peritoneum at the opening of the bowel — are becoming less with the improved technic. The general statistics, however, of the operation of gastro-enterostomy and lateral anastomosis are not satisfactory. Any departure from the routine methods must, in order to gain advocates, be supported either by a large clinical success or by strong experimental evidence. Reports of clinical cases will exert their influence for or against any procedure.

This series of twenty operations on animals, in which the elastic ligature was used, is reported and the literature of experimental work along the same line is reviewed in the hope of adding to the data from that standpoint.



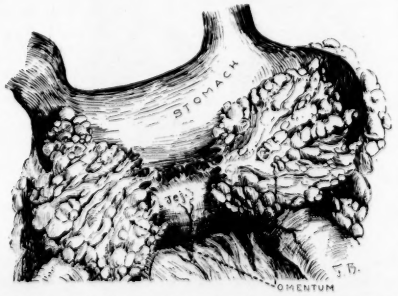
Gaston [1] as early as 1884 used the elastic ligature in forming an anastomosis between the gall bladder and the duodenum. He included within a single stitch of elastic cord or silk various lengths of the wall of the gall bladder and gut, and supported this stitch with a circular row of Lembert sutures. His experiments were employed solely with the question of an anastomosis between the gall bladder and gut. He demonstrated the possibility of effecting an opening between hollow viscera by means of pressure necrosis, but in connection with this gastro-intestinal work the experiments are interesting only on account of the question of priority of ideas and to emphasize the fact that in a thin-walled viscus, such as the distended gall bladder, the method is of questionable utility, because under pressure there may be an escape of the contents at the application of the ligature or the ligature may cut through too soon.

In 1888 Bardenheuer [2] published an inaugural dissertation in which he reported successful results in gastro-enterostomy on animals by the use of an elastic ligature. As quoted by Terrier and Baudouin [3] the elastic ligature used was 1 to 1.5 mm. in diameter and the bowel was taken up in small separate loops until the required amount, about 1 cm. for a gastro-enterostomy, had been included. The opening was complete at the end of two days. His work apparently at that time did not excite sufficient interest to be either confirmed or refuted.

McGraw [4] presented before the American Medical Association in 1891 the results of experiments on twenty-four dogs in which a gastro-enterostomy had been done by means of an elastic ligature. A second series was for relief of fecal fistulæ by lateral intestinal anastomosis, and a third was to make an opening of the gall

The stomach and jejunum have been approximated with a continuous suture. The elastic ligature has been passed through the gut walls. The "knot" introduced in the second series of experiments is seen at the middle of the ligature.

The elastic ligature has been drawn tight and the first part of the square knot is held by means of a silk ligature. The wall of the stomach included within the loop of the ligature is thickened rather than wrinkled, while the jejunum is markedly wrinkled. The "knot" in the middle of the ligature has been buried by the folding over of the serous surfaces.



*I wish to express my thanks to Messrs. J. B. Hartwell, L. C. Kingman and W. G. Lee, members of the graduating class of the Harvard Medical School, for their assistance in this work.

bladder into the duodenum. He selected a round rubber cord 2 mm. in diameter, after experimenting with a flat band and a larger cord. The salient points of the technic are that the ligature must be on the stretch when drawn

Interrupted stitches have been placed anteriorly, and at the ends of the loop, completely burying the elastic ligature.

through the gut, the whole extent of gut to be cut away is to be included within a single loop; the ligature is to be prevented from slipping when tied by tying a silk stitch across the two halves of the square knot; the serous coats are to be approximated by a supporting circular row of Lembert stitches. Detailed data are not given, but the results showed to McGraw's satisfaction that the changes which followed the application of the elastic ligature were as follows:

Three days after operation, the omentum has become wedged in at either end of the line of suture, and adhesions have formed between the stomach and jejunum.

At the end of twenty-four hours the corrugations caused by the wrinkling of the gut wall began to disappear, but there was no evidence of a cutting through of the ligature. The folds due to the wrinkling of the gut wall were entirely gone at the end of forty-eight hours and there was a slight cutting through of the tissues by the ligature. A small patent space on either side of the ligature existed at the end of the third day. At the end of the fourth day there was a complete cut-out of the ligature, the opening being equal to the extent of the gut included by the loop. Exceptionally the cut-out was found complete at the end of three days, or the ligature was found at the end of five days still surrounding a bridge of tissue. With his experimental animals no difficulty was experienced from the formation of adhesions across the anastomosis. He assumed that the mucous membrane crowded together as the ligature cut through, thus making a smooth surface with a complete covering of mucous membrane. While not the first to employ the elastic ligature as the means of anastomosis between the stomach and intestine McGraw without doubt overcame the technical errors of Bardenheuer and made the method practical.

Cordier [5] in the same year reported experiments on fifteen dogs which confirmed completely the results of McGraw. No detailed data are given of the work.

Just as McGraw had done his work independently of that of Gaston and Bardenheuer, so Podrez,[6] in 1898, published a so-called new method of intestinal anastomosis. He used two silk ligatures applied in the form of a Greek cross and from experiments on nine animals concluded that the method was satisfactory and that the cut-out occurred in two to four days. Generally the experiments incited by this paper failed to confirm Podrez's results.

Modlinski [7] in the following year modified the method of Podrez by substituting an elastic ligature for the silk and obtained satisfactory results in a series of nine dogs. He estimated the time necessary for a cut-out to be two days.

Cutts, [8] in 1901, published results of animal experiments with the elastic ligature. He used no supporting sutures, yet had no peritoneal infection and obtained free openings. The time of the cut-out and other details of the procedure are not given.

The two recent publications of experiments are by Kakels and Maury. Kakels [9] operated upon ten dogs with the following results. One died within the first twenty-four hours. The peritoneal cavity was clean. One killed the third day, one the fourth day, one the fifth day and one the seventh showed a partial cut-out of the ligature. Two killed on the fifth day and one on the eighth showed a complete cut-out. Two dogs were living at the time his report was made. There was no case of peritonitis, and no newly made adhesions across the lumen were noted. The opening showed no tendency to contraction. He used ligatures of 2, 3 and 4 mm. in diameter and would prefer a larger rather than a smaller cord.

The article by Maury [10] is devoted rather to suggesting a modification of technic than to testing the results of the elastic ligature as

FIG. 1. — Section across the mass of tissue enclosed within the loop of the elastic ligature, 5 days' duration, showing pressure necrosis due to the elastic ligature.

FIG. 2. — Section at right angles to the line of union of the stomach and jejunum, 12 days' duration, showing an area of granulation tissue between the two viscera, with the mucous membrane growing over it from either margin.

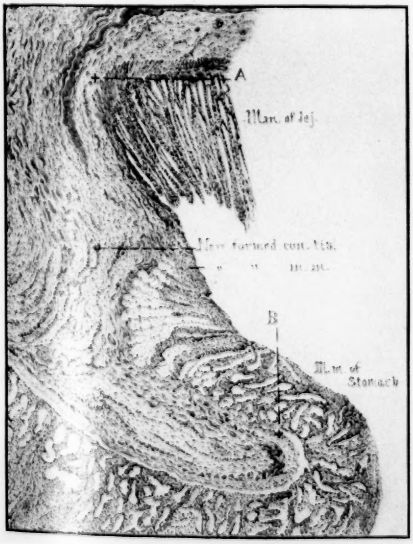


FIG. 3. — Section at right angles to the line of union of the stomach and jejunum, 30 days' duration, showing fairly dense scar tissue completely covered by new formed mucous membrane. A, point at which submucosa of jejunum has been cut through; B, point at which submucosa of stomach has been cut.

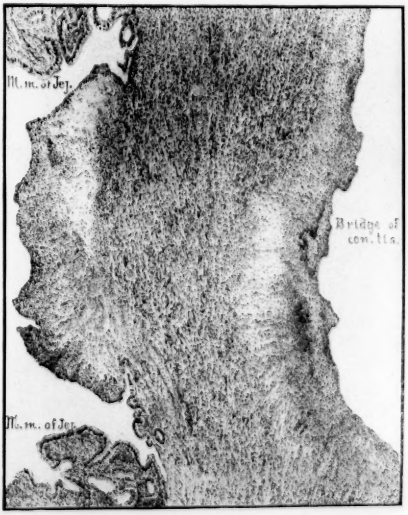

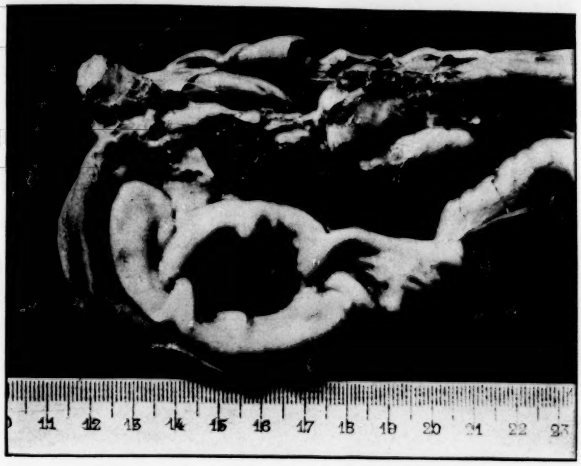

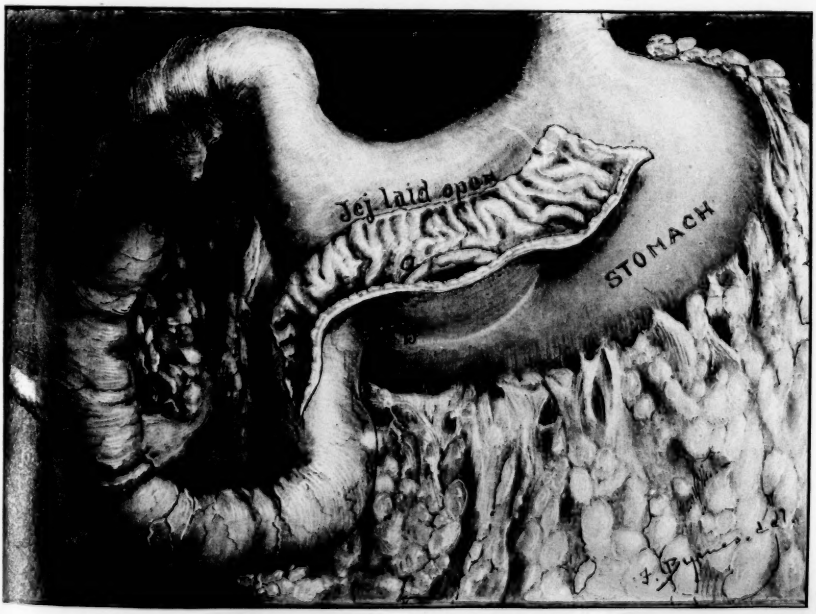

FIG. 4. — Section across an adhesion, 7 days' duration, which had formed between the edges of the jejunum after the elastic ligature had cut out

Photograph to show the actual opening made by means of the elastic ligature between the stomach and jejunum.

Thirty days after operation, the adhesions of the omentum have practically disappeared and the external line of union between the stomach and jejunum shows as a fine line. A, internal line of union; B, external line of union.

applied by McGraw. Maury states that in a series of preliminary experiments two bands of tissue were always found across the opening and this led him to change McGraw's method so that an actual hole would be punched out of the gut wall. Instead of including the tissues within a single loop the ligature was passed back and forth so that a triangular or square area was included. With this modification the 2 mm. elastic cord was used on twenty dogs and one pig. Six of the dogs died — one from intestinal obstruction, two where no stitches had been used from perforation at the site of the ligature, one from a small perforation away from the ligature, and one from a septic stitch-hole three and one-half months after operation. Three dogs and a pig were living and well at the time of his report. No adhesions across the anastomosis were noted in the remaining cases. Maury concludes that with his modification the operation is much improved and it is a satisfactory procedure. No data as to the time of the cut-out are given. Emphasis is placed on the necessity of supporting Lembert stitches with this modification since by the repeated passing of the ligature there may be some contamination of the peritoneum.

On the whole the published experimental work confirms the claims made by McGraw in 1891. To summarize it may be said that it is agreed that the elastic ligature will cut its way out; a firm and smooth union of the opposed serous surfaces is formed; and the operation is performed with the miminum risk. The time of the cut-out and liability to the formation of adhesions across the opening must be determined by further evidence.

Variations in the time of the cut-out may in a measure be attributed to the degree of elasticity possessed by the ligature which depends not only on the original quality but also on the amount of degeneration from age. The personal equation of the operator must also be considered. The individual resistance of the tissue in different cases is not to be overlooked. My own experiments are as follows:

The elastic ligature was used on nineteen cats and one dog, the operations including nineteen gastro-enterostomies and one entero-enterostomy. The general principles of McGraw's technic were observed; that is, the ligature was on the stretch when pulled through the gut, the ligature included in a single loop the entire amount of the gut to be cut away, the ligature was secured by tying a strong silk thread around the two parts of the square knot. Supporting circular rows of Lembert stitches were used in all but one case, a continuous or interrupted one posteriorly and an interrupted one anteriorly and at the ends. The ligature used in all but two cases was a rubber cord 3 mm. in diameter. A smaller size, 2 mm., did not seem to constrict the large amount of tissue satisfactorily and a 4 mm. in addition to being too bulky did not cut through any more rapidly than the 3 mm. cord. A common darning-needle with a long but narrow eye served as a carrier for the ligature. Unless otherwise stated in the tabulation the operation done was a gastro-enterostomy and the length of the gut wall included in the loop was 5 cm. The experiments may be divided into two main groups: first, one in which the elastic loop contains but one knot; and second, one in which an extra knot was tied in the cord so that there was a knot of rubber at either end of the loop.

The following table includes the operations in which the loop contained a single knot:

Time Elapsed After Applying Ligature.	Operation.	Postmortem Findings.
1 day	Pylorectomy with lateral anastomosis between closed stomach and jejunum. 5 cm.	No cutting through of ligature. Fine adhesions formed between the opposing serous coats.
4 days	Gastro-enterostomy. 5 cm.	4 mm. cord. Mucous membrane of jejunum cut through. No opening into stomach.
4 days	Gastro-enterostomy. 5 cm.	Knot had cut through into jejunum. Opening into stomach admitted probe.
5 days	Gastro-enterostomy. 5 cm.	Knot had cut through into jejunum. Artery forceps can be passed into the stomach.
5 days	Lateral anastomosis between two loops of jejunum. 5 cm.	Ligature still around a bridge of tissue, but an opening 2 cm. in length was formed.
6 days	Gastro-enterostomy. 5 cm.	Jejunum entirely cut through. Stomach wall completely cut through for only 5 mm. at the knotted end of the ligature.
9 days	Gastro-enterostomy. 2.5 cm.	Ligature still around the bridge of tissue. Complete cut-out in the stomach cavity of 1 cm.
9 days	Gastro-enterostomy. 4 cm. in loop	Ligature still around the bridge of tissue. Complete cut-out in the stomach of 2.5 cm. Mucous membrane of both jejunum and stomach cut for 3.5 cm.
12 days	Gastro-enterostomy. 5 cm.	Full cut-out of 5 cm.
13 days	Gastro-enterostomy. 5 cm.	Ligature all but cut out and hanging by small pedicle. Bridge of tissue partially obstructed opening so that free passage was only 1.5 cm. in length.
30 days	Gastro-enterostomy. 5 cm.	Full cut-out of ligature. Opening 4 cm. in length.
30 days	Gastro-enterostomy. 5 cm.	4 mm. cord. Cut-out 3.5 cm. in length.
30 days	Gastro-enterostomy. 5 cm.	(No supporting stitches) Ligature had cut-out. Opening contracted to 2 cm. in length.
In the following two cases an attempt was made to cut away a part of the serous and muscular layers of the wall of the stomach and jejunum before applying the ligature, in order to reduce the amount of tissue to be cut through.		
3 days	Gastro-enterostomy. 5 cm.	No apparent cutting through of the ligature.
9 days	Gastro-enterostomy. 5 cm.	Bridge of tissue surrounded by the ligature. Free opening 2.5 cm. in length.

This series demonstrated that the stomach of the cat was very resistant. The jejunum was cut away by the fifth day, but not until about the twelfth had the ligature completely cut out the stomach wall. The stomach and intestinal walls of the cat at once attract attention by their bulk and firmness and to this resistance the delayed cut-out was attributed rather than to any alteration in the prescribed technic. The rubber cord, 4 mm. in diameter, was no more effective than the 3 mm., although both were new and of the best quality of rubber. Removing the outer coats of the bowel did not seem to aid materially in the rapidity of the cut-out and complicated the operation.

In all cases it was noticed that the greatest cut-out was at the end of the loop where the ligature was knotted. Acting on this hint the technic was modified. A square knot was tied in the middle of the ligature and a needle threaded on either end. In this way a knot of rubber was formed at either end of the anastomosis.

The tabulation of the results with this change is given below. All these operations were gastroenterostomies and 5 cm. of the gut wall was included within the elastic loop, which contained two knots.

Time Elapsed After Applying Ligature.	Operation.	Postmortem Findings.
3 days	Gastro-enterostomy. 5 cm.	Ligature still around a bridge of tissue. Two openings between stomach and jejunum, the largest of which was 2 cm. in length.
4 days	Gastro-enterostomy. 5 cm.	Jejunum completely cut through, but stomach holding by a thin film of tissue. Free opening of about 1 cm.
5 days	Gastro-enterostomy. 5 cm.	Complete cut-out of 5 cm.
5 days	Gastro-enterostomy. 5 cm.	(Dog) Complete cut-out 5 cm. in length. Ligature hanging by shred.
7 days	Gastro-enterostomy. 5 cm.	Ligature is completely cut through. Small bridge of tissue across the opening.

With the knotted ligature even with the resistant tissues of the cat the anastomosis was completed by the fifth day and at the third or possibly before an opening of considerable size existed.

Eighteen of the cats were killed with chloroform and two died as the result of the operation, the case of pylorectomy never rallying from the shock and a gastro-enterostomy dying on the ninth day from a septic wound of the belly wall. In every case, except the one with the sloughing abdominal wall, the general peritoneal cavity was clean. Two cases showed bands of tissue extending across the opening after the ligature had completely cut out. The first was evidently caused by an error in technic in not including all of the mucous membrane within the loop; that is, in passing the needle into the bowel a fold of the membrane was transfixed. This is so interpreted because there was no evidence that the mucous membrane had been cut through. In the second case the bridge showed under the microscope unmistakable granulation tissue on its center and must be considered as an adhesion between the cut surface of the gut after the ligature had cut its way out. The serous surfaces uniformly after the first two days had practically lost all of the wrinkles produced by tying the ligature which were noted at the end of the operation. The stomach wall included by the ligature thickens by contraction rather than wrinkles, hence there is no reason why it should not be smooth when the anastomosis is completed. The duodenum on the other hand is markedly wrinkled and I cannot explain the reason of the early disappearance of the folds. Adhesions of the omentum about the site of the suture were present in the cases which were killed in the first few days, but grew less and less as time went on, until at the end of a month they were not marked.

The time of the cut-out varied between rather wide limits — five to twelve days. The delay may be attributed to the marked resistance of the tissues of the cat. With a knotted ligature, however, the time was reduced to within the limits of other observers, four to five days.

Figure No. 1 illustrates the process of the cut-out by pressure necrosis. The steps as seen microscopically are, first, necrosis and rupture of the muscle fibres; second, an invasion of leucocytes, and, finally, solution of the tissue.

The union is effected between the serous surfaces by the slight inflammatory process incident to the injury and pressure necrosis.

Other writers have assumed that no raw surface was left after the cutting through of the ligature, but Figure 2 shows an area of granulation tissue between the serous surface over which the mucous membrane is extending from either side. Figure 3 illustrates the end result with the granulation changed to scar tissue and the entire margin of the hole completely covered by mucous membrane.

That adhesions may form between the raw surfaces is shown by Figure 4 which is a section through such a bridge. In the center new formed tissue is plainly evident which can be accounted for in no other way. The danger of this, it seems to me, has been rather overstated by certain observers. While the possibility exists, it has not been found generally to be a probability. There is no reason why in the use of the ordinary intestinal suture the same complication under exceptional conditions might not arise.

In the application of the ligature the simple technic as described by McGraw is, in my opinion, adequate and satisfactory. Any elaboration of technic must reduce the effectiveness, because it reduces the speed, thus adding to the shock, and increases the liability of infection. As to the supporting sutures, a posterior continuous possesses the advantage of quicker application, but anteriorly and at the ends an interrupted stitch would seem to be preferable. For while

on animals it was not demonstrated that a continuous anterior stitch tended to contract the opening, since it is applied after the jejunum has become wrinkled, such is the case on the cadaver. In trying the ligature care should be taken not to include the posterior suture within the loop. Since it was possible to include 5 cm. of the wall of the small intestine of a cat the larger human bowel will permit of the formation of an opening up to any size which may be required to side track the stomach contents.

Conclusions. — These experiments show that a successful anastomosis between the stomach and intestines, or two loops of intestine, is possible by means of the elastic ligature. The method is not applicable when an immediate opening is required.

The time of the cut-out varies, depending upon the character of the ligature, the method of application, and the resistance of the tissues in any case, but the ligature will ultimately cut out.

A knot at either end of the elastic loop increases the rapidity of the cut-out.

The pinching of the gut by the ligature seems to cause no bad symptoms.

The serous surface of the outside of the joint when completed is smooth.

The anastomosis by gross or misroscopical examination shows no evidence why there should be any greater tendency to contraction of the opening than with the ordinary methods of intestinal suture.

The procedure causes a minimum operative risk, both as regards shock and infection.

Adhesions across the opening are a possible, but not a probable, complication.

Extending these conclusions to practical operative work, it is my opinion that in cases in which an immediate opening of the bowel is not imperative, and in which the avoidance of operative shock is an important factor, the elastic ligature may prove to be the operation of choice in gastro-enterostomy and lateral anastomosis.

DIFFERENTIAL DIAGNOSIS OF RHEUMATISM AND THE ARTHRITES.[1]

BY THOMAS F. HARRINGTON, M.D., LOWELL, MASS.

THERE is, perhaps, no class of affections more commonly met in practice than those included in the title of this paper. Notwithstanding this marked prevalence, the ancient history of its recognition, and the great progress in scientific medicine, the undisputed fact remains that there is no one term in medicine accountable for more ignorance and neglect than "rheumatism." Undefined itself, it has spread its mantle over conditions dissimilar and obscure until it has become well-nigh impossible to separate the true from the spurious. It is the hope of pointing out some of the errors and evil consequences of this classification that prompts me to present the subject at this meeting.

In the first place rheumatism and arthritis are not synonymous terms. The characteristic symptom of rheumatism is an arthritis, yet we have many arthrites which cannot be associated with rheumatism as clinically accepted. Every arthritis should be traced to its probable true cause, and no case should be considered rheumatic unless an undisputed attack of acute rheumatism can be given. Rarely is rheumatism diagnosed other than it is; the danger lies wholly in the opposite direction. As will be shown later, there is probably but one form of rheumatism, namely, acute rheumatism. Any other use of the term leads to confusion, and often to wrong treatment, with disasterous consequences.

It is with the object of avoiding such errors, as well as an endeavor to offer a classification founded upon clinical appearances, re-enforced by etiological and pathological findings, as far as known, that I would suggest the following:

A. Infective arthritis: (1) acute rheumatism; (2) gonorrheal arthritis; (3) purpuric arthritis; (4) pneumococcic arthritis; (5) scarlet fever arthritis; (6) tubercular arthritis; (7) syphilitic arthritis; (8) typhoidal arthritis; (9) influenza arthritis; (10) erysipelas arthritis; (11) spinal meningitis arthritis; (12) smallpox arthritis; (13) dysenteric arthritis; (14) glanders arthritis; (15) pyemic arthritis. *B.* Arthritis deformans. *C.* Osteo arthritis. *D.* Traumatic arthritis. *E.* Gouty arthritis. *F.* Hemophilic arthritis. *G.* Senile arthritis.

On account of the confusion and disputation existing on the question of classification I would offer the following reasons for the above grouping.

Idiopathic arthritis probably never occurs. In infective arthritis there is usually more than one agent, and the effect of the agent is modified by various conditions,[1] *e. g.*, the resisting power of the individual, the dose of the toxin received, and by the presence of other organisms or their toxins. The synovial membrane of joints has a marked tendency to become involved in many of the acute infectious diseases.

This shows itself in four different forms [2]:

First. — By a transient synovitis with limited effusion, *e. g.*, typhoid, scarlet fever, influenza.

Second. — Those with marked swelling and effusion of fluid into the joint which later becomes turbid and purulent.

Third. — Those having involvement of the peri-articular structures, *e. g.*, gonorrheal.

Fourth. — Those cases in which the arthritis is acute and destructive from the start, suppura-

[1] Read before The Massachusetts Medical Society, North Middlesex District, Oct. 28, 1903.

tion is early and violent, *e. g.*, pneumococcic infection.

It is very probable that all organisms which cause arthrites produce other pathological conditions as well.[3] While there are some exceptions yet unexplainable, it can be stated as a general rule that all acute arthrites are secondary manifestations. In doubtful cases the probability of mixed infection must be borne in mind. The role played by the nerves in the course and development of joint affections is very great. The close relation existing between acute rheumatism and chorea, as well as the positive factors, sex, age, mental and nervous fatigue, shock, etc., are, especially in arthritis deformans, open up a wide field for investigation.

In the above classification rheumatism is placed under infective arthritis because it is now generally understood that this symptom complex is due to some form of micro-organism. Walker[4] has isolated a micro-organism which he calls "micrococcus rheumaticus." Other factors tending to establish this relationship are[5]: its endemic and often epidemic nature depending upon climatic conditions; its many manifestations, variety of lesions, fever and sweating resembling tuberculosis and pyemia; its tendency to recur, especially upon exposure, resembling pneumonia and erysipelas; its liability to relapse like enteric fever, and to end spontaneously as do the exanthemata. Then, too, the close relationship between affections associated with follicular tonsillitis and those associated with rheumatism, namely endocarditis, pericarditis, pleurisy, chorea, erythema nodosum, as well as other cutaneous and subcutaneous effusions such as purpura, pneumonia, peritonitis and profound anemia. The occurrence of arthritis, pleurisy, etc., with puerperal sepsis also points strongly to the septic association of rheumatism.

There seems to be as little foundation for the term rheumatic diathesis, or uric acid diathesis, under such a classification as there would be to speak of a pneumonic or septicemic diathesis. The uric acid condition has been demonstrated in athletes in whom no suspicion of rheumatism or gout existed.[6]

In the classes arthritis deformans and osteo-arthritis a distinction is made between those cases in which there is a true bony enlargement of the joint and those in which the deformity is due to an atrophy of the surrounding tissues, causing an apparent rather than a real enlargement. The former class is a true osteo-arthritis and is so-called. The latter is a deformity due in all probability to some trophic change depending upon disturbances of the nervous system.

The clinical signs and pathological findings of each are different and characteristic. As the treatment of the two affections is very different it is essential that this distinction be recognized. It is the failure to do this that has resulted in so many permanent cripplings, also salicylic acid poisoning.

Whether arthritis deformans, like some other conditions, results later in osteo-arthritis does not alter this classification. The point is that all joint affections which have true overgrowths should be called osteo-arthritis, the suffix deformans being understood; the term arthritis deformans being limited to the conditions characterized by appearances quite typical and constant to be described later. Much confusion in reading textbooks and medical literature will be avoided if some such distinction is maintained, and if the term rheumatism is limited as signifying a clinical picture unlike any other joint affection, rather than an arthritis occurring in the course of many diseases. This would eliminate all such terms as muscular rheumatism, tuberculosis rheumatism; scarlatinal, gonorrheal, gouty, typhoidal, etc., with the suffix rheumatism.

DIAGNOSIS.

Infective arthritis. — There is usually a history of a primary infection to which the arthritis is secondary.

In the case of acute rheumatism, the following signs are characteristic: (1) *History.* —Often follows tonsillitis, especially the suppurative form. In the majority of cases the previous health is good and there is entire absence of any constitutional disturbance. In 270 cases occurring at Johns Hopkins Hospital, 60% occurred between ages of eleven to thirty years; 30% occurred between the ages thirty to fifty years. There was a family history of rheumatism in 25% of the cases; 45% had had previous attacks.[7] The onset is sudden and without a chill in 94% of the cases in the Johns Hopkins series. Cold, damp weather and exposure are factors but do not cause rheumatism.

(2) *The character of the inflammation.* —Rapid development of pain, swelling and heat in one or more joints. In twenty-four hours after onset the temperature ranges from 102° to 104°, with a pulse which is more apt to be under than over 100. The temperature is not remittent, thus differing from most of the other arthrites, and it has very slight depressing action on the central nervous system.

(3) *Pain.* — As it attacks a new joint it always leaves the old one, and it is this flitting from joint to joint which often serves to distinguish it from other diseases.

(4) *Results.* — It runs an acute course, averaging three to six weeks, with a marked tendency to get well. It does not deform the joints, *i. e.*, the joint is left as uninjured as it was before the attack. The endocardium is involved in fully 60% of the cases. It tends to recur. It never suppurates. It rarely becomes chronic.

In 100 cases of alleged chronic rheumatism lately examined by the writer, only 19 gave a history of a previous acute rheumatism. In 14 of these, closer questioning or the result of the examination threw considerable doubt upon the nature of the primary attack.

The term "chronic" relates entirely to time, therefore chronic rheumatism, so-called, implies

a long continued or slowly progressing rheumatism. This we know is not the nature of infective rheumatism.

The term *recurrent* is more truly descriptive of the majority of these cases. Such cases may eventually result in deformity, but they then become osteo-arthritis, and should be so called and treated. Any case of acute arthritis which leaves the joint impaired, or which fails to yield to salicylates should excite suspicion as being something other than pure rheumatism. Such cases will usually be found to be due to some other toxin or to some blood or nerve dyscrasia.

Among the conditions most commonly called chronic rheumatism are [8]: (1) relaxed ligaments (flat foot). (2) Occupation neuroses, which are usually worse in damp weather, and which are not peculiar to any special occupation, but occur when faulty positions throw unusual amount of work upon any one set of muscles. (3) Neuritis, due to circumflex nerves sending trophic fibers into the joint. (4) Gout which is more common in this country than supposed, *i. e.*, it is three-fourths as frequent at Johns Hopkins as at St. Bartholomew Hospital, England; most common among lead workers and beer drinkers. The differential diagnosis of acute rheumatism and acute gout is very difficult. The gouty nodules in the ears, or tophi on the fingers are characteristic of gout. (5) Multiple neuritis is often mistaken for rheumatism, but the absence of knee-jerk and the alcoholic history, as well as the future course of the disease serve to differentiate them.

Chorea and acute rheumatism are closely allied. The concensus of opinion to-day seems to point to chorea being a manifestation of cerebral rheumatism in which the infective agent has acted upon the serous membrane of the joints and brain, and has also reached the cortex itself, thus producing convulsive movements.[9] This is in contra distinction to the theory that some infective agent acted directly upon the nerves themselves. The increased reflexes noted in rheumatism are probably due to the same cause.

In gonorrheal arthritis the history is important. It is often limited to one joint, especially the left knee, and is not as painful, has less fever, and does not go from joint to joint. The inflammation is in the peri-articular surface and extends along the tendons. The effusion is rarely purulent, although suppuration of the sheaths may be found. This is important in a bacteriological examination of the joint as colonies of gonococci can be obtained in cultures taken from the outgrowths on the synovial membrane while the fluid fails to show their presence.

In opthalmia neonatorum arthritis has occurred which yielded promptly and completely on curing the conjunctival discharge. In the multiple gonorrheal arthritis it is often hard to differentiate. It is usually confined to the lower extremities, and often attacks the sterno-clavicular, the intervertibral, the temporo-maxillary and the sacro-iliac articulations, joints rarely involved in acute rheumatism. The possibility of this form of arthritis in newly married women infected by an old gleet of the husband should be borne in mind. Gonorrheal arthritis is most intractable and this often serves to distinguish it from rheumatism. It is far safer to regard atypical or doubtful arthritis as being of gonorrheal origin than due to rheumatism.

There is nothing characteristic in the blood in rheumatism, notwithstanding the marked anemia so often associated with it.

In arthritis occurring with purpura, the existence of urticarial wheals in addition to other signs of purpura is usually sufficient to distinguish it from rheumatism. Sore throat and even pericarditis may occur in this form of arthritis.

Arthritic manifestations in pneumonia indicate a general pneumococcic infection and have a mortality of 60%.[10]

The arthritis occurring in scarlet fever is not rheumatic. Recent investigators [11] ascribe the joint trouble to streptococcus pyogenes, and consider it one of the manifestations of scarlet fever, rather than a rheumatism complicating the disease. It usually attacks the wrists and fingers, or other small joints. In the monarticular form there is a greater tendency to suppuration.[12] The arthritis occurs most often at the end of the second week before desquamation sets in.

Lately French writers [13] have described arthritis occurring in connection with lupus, as tuberculous rheumatism but which had better be called tubercular arthritis. This is painful and always slow in developing, although there is usually a history of traumatism from which the family date the trouble. The family history of tuberculosis or the presence of tuberculosis in other parts of the body is important. There is usually very little fever. The joint enlargement is soft and symmetrical. Monarticular rheumatism is more often regarded as tuberculosis than the contrary. A mixed infection of these two conditions is not uncommon. Joints in defective positions, with abscess or fistula, accompanied with muscular atrophy, justify the diagnosis tubercular arthritis. This form of arthritis closely resembles the syphilitic arthritis. The latter is usually limited to one joint and is painless, or painful only at night. A characteristic point about this class of syphilitic affections is that the amount of movement preserved by the joint is far greater than in any other joint affected by the same amount of disease. In doubtful cases the history and therapeutic tests are important aids.

Syphilis attacks the joints symmetrically and it rarely relapses, thus differing from rheumatism.

As to arthritis of the spine associated with typhoid, the conditions most likely to resemble it are myelitis, sciatica, hip-joint disease, tumors of pelvic bones, bone disease, malingering or muscular pains, and pachymeningitis.

Arthritis occurs in connection with influenza

erysipelas, smallpox, appendicitis, spinal meningitis, dysentery and glanders, but in none is there much resemblance to acute rheumatism with its sudden onset, its joint to joint evanescence, never suppurating, and always leaving perfect joints. There is, however, one form of infective arthritis which closely resembles acute rheumatism, and upon the differential diagnosis of which serious consequences depend. I refer to *acute osteo-myelitis.*

There is, perhaps, no more serious condition in which rheumatism should be positively excluded than in acute-osteo myelitis. We must be able to recognize this disease in the first forty-eight hours if we expect the best aid from the surgeon. There is a pocket of pus in the bone and if it is not immediately drained, absorption, high temperature, delirium and septicemia follow, resulting often in death, or at the very best in destruction of the bone.

The symptoms that distinguish acute osteo-myelitis from acute rheumatism are classical. Chill, acute pain followed by high temperature, sepsis with its symptoms of absorption, delirium and death. The pain is usually in the extremities of long bones. Usually, especially in children, there is not an effusion into the joint near the focus in the first forty-eight hours. This is different from rheumatism in which effusion occurs in first few hours. The greater intensity of local symptoms, the involvement of the epiphysis rather than the joint, and the more constitutional disturbances are all characteristic.

In the first forty-eight hours pain and sepsis increase but there is no local sensitiveness. Deep and continued pressure for two minutes elicits excruciating pain and frequently indicates the seat of the infection.[14] There is a board-like infiltration of skin and muscles with subsequent involvement of joint and suppuration. Most of the cases occur between puberty and twenty-five years. The favorite seats are head of humerus, lower end of femur, and upper end of tibia. Monarticular pain in children should suggest osteo-myelitis. If there are scars of former operation over the bone the pain is probably a second attack of osteo-myelitis. In many cases there is an existing furuncle, traumatism without external lesions, skin wounds, or one of the infective diseases.[15]

In doubtful cases aspiration is justifiable. The disease may simulate typhoid fever. Blood examination may be helpful in the diagnosis. There is a decided leucocytosis in the early stages of osteo-myelitis, thus differing from typhoid and rheumatism.

No acute arthritis occuring in connection with a possible pyogenic infection should be looked upon as rheumatism or gouty until osteo-myelitis has been positively excluded.

The chronic form of osteo-myelitis is often diagnosed chronic rheumatism, but the localization of the pain in the bone rather than in the joint, and the evidence of necrosis will often serve to differentiate them.

Arthritis Deformans.

This is a good descriptive term and has the advantage in eliminating all reference to rheumatism and gout. It is probably due to some nerve disturbance, and is an apparent enlargement of the joints due to the atrophy of the muscles and inter-articular cartilages. It closely resembles rheumatism is its acute stage, and may occur in combination with acute rheumatism, but it is not caused by rheumatism. It is non-inflammatory and may occur without pain. There is seldom redness or tenderness. It is rarely monarticular, and it never suppurates. There are no true bony enlargements. The characteristics of arthritis deformans are: the spindle-shaped appearance of the joints, its soft boggy feeling, its symmetrical development, beginning in the small joints and spreading without leaving the first joint, its stationary character, never flitting from joint to joint, and always leaving the joint deformed. It is less painful than rheumatism and has a tendency to attack young and middle aged women, especially when there has been any wear and tear of the nervous system. It often comes on insidiously, lasts months, and does not involve the heart. The process stops grating and ankylosis, with resulting deformity, is left. The deformity is usually one of extension or flexion, seldom lateral. In the polyarticular form of any arthritis which does not leave the joint uninjured, especially if the pain and disturbance are more annoying when the patient is worried, or under a nervous strain, we should suspect this form of arthritis. Gout is excluded by the absence of deposits of urates. The so-called Charcot joint is in all probability one of this class. It is readily recognized by the history of tabes as well as the increased lateral movement of the joint without pain. Intermittent hydrops,[16] characterized by painless swelling of sudden onset, without heat and redness, is probably due to some vasomotor neurosis.

The form of arthritis described by English observers,[17] as acute rheumatoid arthritis, confounds acute rheumatism and arthritis deformans more often than any other affection. In this disease occurring in young women a distinction is made in the swelling beginning in the proximal phalangeal joints, extending beyond the affected joints, and becoming fusiform in shape. Other joints become affected until the patient is helpless. There is much muscular wasting or atrophy. It runs a definite course, lasting about three weeks. It attacks the fingers first and spreads to other joints, involving the temporo maxilliary and spinal joints, and it leaves the joints immobile and enlarged, points which clearly eliminate acute rheumatism. Its association with influenza, parotitis, and the like, would suggest a microbic origin, acting no doubt through the nervous system, producing trophic changes in the joints, resulting in arthritis deformans. It is neither rheumatic nor osteo-arthritic.

There are seldom any adhesions in arthritis

deformans. Contractions and stiffening from faulty posture, and extensive degenerative erosions of the cartilages may result. These must not be mistaken for true bony growths which are the characteristics of osteo-arthritis.

Osteo-Arthritis may result from many causes. It may start without any known cause. The disease is essentially a chronic disease, the so-called acute painful period being due in all probability to a double infection. At first there is very slight deformity, and often the person is unaware of any enlargement on account of the gradual development of the disease. The pain is more often at night and is considered rheumatic. It usually affects the large joints (knee), and is often unilateral. It is a true bony growth, "ring bone," and locks the joint mechanically by the formation of osteophytes at the ends of the bones. Change of position often aggravates the pain, especially in the spinal form, and the person walks with a characteristic gait. This serves to distinguish this form from lumbago. The disease is more common in men, especially old men, but it does occur in young people. The true nature of the disease is obscure. Cold and damp may be factors in the etiology, but they do not cause the disease. There is less atrophy of muscles and less synovial swelling than in arthritis deformans. The enlargements are bony and not cartilaginous. The joint capsule is relaxed. The deformity is due to the hypertrophied tissue, as well as to enlarged bone. These hypertrophies have a tendency to form on the dorsal side of the joint, causing a lateral deformity or flexion, thus differing from the deformity of arthritis deformans which is usually one of hyperextension.[18]

In osteo-arthritis due to the presence of Heberden's nodes a very slight injury will often set up an active process resulting in increased deformity and a permanent disability far in excess of that expected from a light blow. The presence of Heberden's nodes in other joints will often confirm this fact. Such nodes suggest strongly the presence of osteo-arthritis, rather than arthritis deformans, and are valuable in deciding the diagnosis, prognosis and treatment in a given deformity.

In arthritis deformans there is practically a false ankylosis which is amendable to proper manipulations, while in osteo-arthritis any manipulations of the joint would most likely break off some of the osteophytes with increased irritation in the joint.

A form of osteo-arthritis occurring in the spine, *spondylitis*, is far more common than supposed.

There may be little or no subjective symptoms referable to the back, and there may be much overgrowth of bone without any marked deformity. The deformity is greater in the slowly developing cases than in the more active process, and its nature depends upon the surface of the bone affected. These cases are usually diagnosed lumbago or rheumatism. The different motions of vertebral articulations should be tested in every case of backache, especially when such is aggravated by change of position, and associated with neuralgic pain, or sensory disturbances in the legs. Even in the early stages there is a "spot" in the spine at which the pain is localized. It can be differentiated from Pott's disease by the pain being local, rather than referred or abdominal, as in Pott's. In doubtful cases the use of tuberculin and the Rontgen rays are helpful. If paralysis has supervened it is peripheral in spondylitis while that due to Pott's disease is paraplegic.[19]

In spondylitis the paralysis is seldom equal on both sides. There is often an associated ankylosis and fixation of the thorax. As the disease advances the tissues shrink and pressure on the cord and nerve roots is released. This results in the abatement of the nerve symptoms, and is often mistaken for an improvement in the osteo-arthritis with an unfortunate relaxation in following the prescribed treatment.

Traumatic Arthritis. — The history of the case is important, care being taken that the trauma is not the exciting cause of an osteo-myelitis or other infectious arthritis, rather than the cause of a simple arthritis. There is usually water in the joint in traumatic cases. Joint mouse or floating cartilage belongs to this class.

Gouty Arthritis. — Many arguments can be offered in support of the theory that gout is due to the destruction of leucocytes in their battle with toxins rather than to uric acid.[20] This brings it nearer to the infective group of arthrites. The characteristics of gouty arthritis are sudden onset, especially at night, often disappearing in day time, also the presence of deposits in the ear (tophi). It attacks usually single small joints. A distinction should be made between a scanty urine with high specific gravity which is permanently so, and one with the same characteristic dependent upon exercise, diet, etc. In chronic gout ulcerations often occur about the finger joints, from which urate of sodium crystals can be collected.

Hemophilic Arthritis. — This should be kept in mind especially in arthritis suggesting surgical interference. A recent writer reports 252 cases.[21] Traumatism does not seem to be an artiological factor. The joint becomes distended with blood. There is a feeling of tension and pain, but no tenderness or symptoms of inflammation. Echymosis in a few days followed with apparently full recovery. This condition soon recurs and results in thickened and roughened synovial membrane, structural changes in the joint, muscular atrophy and resulting deformity resembling osteo-arthritis. The disease occurs usually between the fourth and sixth years and most often in males. The joints affected are knee 50%, elbow 25%. The mortality in hemophilics is less among those having arthritis than among the others. It is 60% in the latter class.

In *Senile Arthritis* there is a thickening of the capsule, but not of the bones. It has no relation to rheumatism and is more stiffness than

soreness. It does not involve the heart and grows better as the day progresses.

Rheumatism in children differs somewhat from that of adults. The tonsils are the most common source of suspected infection. The arthritic symptoms are not as well marked as in adults, and are more apt to come on insidiously. Recurrent tonsillitis, chorea, erythema, or nose bleed, are often associated with arthritis. Continued fever with slight remissions suggests endocarditis.[22] There is not the same successive involvement of joints seen in adults. The family history, or a history of "growing pains," especially if accompanied with even slight swelling (fibrous nodules) suggests rheumatism.

The distinction between rheumatism in adults and that of children is best told by Cheadle, in a single sentence:

"The various manifestations of rheumatism massed together in the case of adults tend to become isolated in the case of children, so that the whole phenomena are distributed over years, instead of weeks or months, and the history of a rheumatism may be the history of a whole childhood."[23]

Clinical Department.

REPORT OF CASES OF DECAPSULATION OF THE KIDNEY.[1]

BY F. G. BALCH, M.D., BOSTON.

THE following cases are reported in the endeavor to add a little to our knowledge of the results obtained by various surgeons in their efforts to cure a disease, which until recently has been considered purely medical, by surgical interference.

CHRONIC DIFFUSE NEPHRITIS. DECAPSULATION.

CASE I. Ellen W., thirty-three, married. Laundress. Entered Massachusetts General Hospital, Nov. 5, 1901.

Personal history. — Unimportant, excepting she has for several years drunk one-half gallon of beer daily. Subject to headaches and vomiting spells.

[1] Read at the annual meeting of the Suffolk District Medical Society, October 31, 1903.

Present illness. — For past two or three weeks severe headache, vomiting and swelling of feet and abdomen. Urine scanty. Diarrhea persistent.

Examination. — Well developed but obese. Heart and lungs negative, except for few râles in back. Much edema of feet, legs, thighs, back and face, with marked ascites. Pulse 70, small volume, low tension. *Urine.* — Acid, 1,009, albumin 2¼%. Sediment, blood, chiefly abnormal, many fatty renal cells, and hyaline, granular and brown granular casts. Quantity in first three days, less than 10 oz.

With daily hot air baths, pilocarpin and purgative treatment she improved slowly during first two months. Amount of urine rising to from 25 to 40 oz. per day. Albumin falling to ¼% on average. Casts and blood corpuscles fewer in number.

During winter very slight improvement. Ascites required tapping.

March 24, 1902. Less edema and ascites.

Occasional headache and vomiting. *Urine* 1,012, smoky. Albumen ½%. Sediment as before, with occasional waxy cast. In spite of this apparent improvement patient's general condition became so much worse that operation seemed advisable.

Operation, March 28 on both kidneys. Tissues edematous, kidneys small, dark, granular in appearance; patient stood operation well. During first three days after operation twenty-four-hour amount of urine rose from 20 to 40 oz. Improvement after operation slow, but less headache and vomiting.

May 1. Less edema, and in legs and feet only, but ascites continues; tapped and 8 qts. of fluid drawn. *Urine* shows fewer casts, hyaline and granular, with fat; fewer renal cells and blood corpuscles; albumen ¼%.

June 1. Patient stronger, appetite improved; still occasional headache and vomiting. *Urine* pale, about 1,010, average 30 oz. in twenty-four hours. Albumen, large trace. Casts same as before, with renal and fatty renal cells, few blood corpuscles. Returned to medical ward June 6. Hot air baths renewed and diuretics, which raised amount of urine to an average of 40 oz. Abdomen requires tapping about once in three weeks. Discharged July 20, 1902, when she felt well, but vomited every few days; had no edema and very little ascites. *Urine* pale, 1,011; albumin $\frac{3}{10}$%. Occasional hyaline casts; renal cells, with fat; occasional blood corpuscles.

Patient returned to hospital in October, 1902. Had felt well since operation and had been doing housework daily, and said that she was better than she had been for a long time.

Urine then showed ⅛% of albumen, with a sediment of a few waxy, many granular casts, with fat adherent; few red corpuscles, and compound granule cells. Patient lost sight of and subsequent history unknown excepting that she died in May, 1903, after considerable excess in alcohol.

CASE II. Mary B. L. Twelve years old.

Etiology. — She had measles, mumps and scarlet fever as a child. She has always been well and strong. Last February caught cold and was at home a week. Two days later her feet swelled and she was edematous below her eyes. She had no headache or disturbance of vision. She had been under treatment since April 16.

Examination. — The tension of the pulse was somewhat increased. There was slight dullness in the flanks shifting on change of position. There was edema of the feet and legs and under the eyes. *Urine.* In the medical wards before transfer she had been secreting from 8 to 10 oz. of urine a day. On the

23d it was 9½ oz.; on the 24th and 25th it fell to a little over 3, and on the 26th, 2 oz. An examination on the 23rd showed the urine to be smoky in color, acid, 1,031, ½ to 1% of albumen. The sediment was typical of parenchymatous nephritis. Urea 3.59%.

Operation. — Dr. Scudder decapsulated both kidneys June 22, 1903, and a fragment removed was reported typical of sub-acute glomerulo-nephritis.

Subsequent history. — Next day Cheyne-Stokes respiration developed but the patient was bright when spoken to and had no headache. On the 24th there was much less edema but great dyspnea. Next day the dyspnea was better, but there was more edema, and on the 27th she died.

Case III. A. S. R., twenty-seven years old. Seen by Dr. A. T. Cabot in consultation with Dr. A. W. Dudley of North Cambridge, on June 10, 1903.

Three years before patient first learned that his urine contained albumen. From that time meat was omitted from diet. One year ago, he consulted Dr. Dudley for swelling of feet.

Examination of Urine. — 1,018, albumen ¼%. Casts hyaline, granular, and fatty; renal cells. Ten months ago stopped work, and has kept very quiet. Has slowly lost strength, and has had slowly increasing edema of dependent parts.

Examination of urine at this time was as follows:— 1,015, much sediment, albumen ¼%; considerable pus since one catheterization; casts about as before, numerous hyaline, sometimes with epithelium adherents; large and small granular. Had a convulsion ten months ago, which was succeeded by nine or ten others, followed by a coma for forty-eight hours. Later, about Thanksgiving, had several more convulsive attacks, followed by a week of coma, thought possibly to be due to a blow on the head. On April 15, two seizures, with coma for twelve or fifteen hours. On May 15, three seizures in six or eight hours; coma for forty-eight hours. Urine always runs up in amount before seizures, and once reached 178 oz. in a day before attack; it decreases immediately after attack. Average amount of urine has shown steady decrease.

Operation not advised, but demanded by patient and friends, who understood the desperate nature of the case and wished to take desperate chances.

Operation June 18, 1902. Much edema in tissues. Large white, mottled kidneys.

Patient made good recovery, but effect of operation on kidneys was practically nil. Gradually lost strength through summer and died early in September. No autopsy allowed.

The average amount of urine after the operation was from 50 to 60 ounces, with considerable variation, at times above 100 oz.

Case IV. Mr. A. G. H., forty years old. Seen by Dr. A. T. Cabot, in March, 1903,.

Albumen had been discovered in his urine first in the year 1900, when he was being examined for life-insurance.

In January, 1902, he was seen by Dr. J. H. Grimes, who found indications of interstitial nephritis, and shortly after that time retinal hemorrhages appeared. Mr. H. rapidly became worse, and during that winter had several slight convulsions, followed each time by a period of somewhat more than a week during which he knew that he was in the hospital, and recognized his friends, but had forgotten much of the immediate past, and did not know how he came to be in the hospital, nor what he was there for. During each of these periods he talked intelligently, but when they had passed, the time was a blank to him. In the latter part of February, and early in March, he had several severe convulsions, which left his mind very much impaired, and it was at this time that Dr. Cabot saw him.

Examination showed right kidney somewhat movable, coming down width of hand below ribs. *Urine.* March 26, 1902, pale, alk. 1,010, albumen, ¼ to ½%. Sediment considerable; pus, small and large round, compound glanular cells. Some abnormal blood. No casts seen.

Operation. — March 27, 1902. Capsule of kidneys more adherent than normal. Kidneys are dark and congested, with a roughly granular surface. Blood pressure immediately after operation, 210.

April 1, 1902. In past two days twenty-four-hour amount of urine has been 88 and 55 oz. respectively. No convulsions except one just after operation. Sediment has become less in quantity.

April 4, 1902. Albumen had fallen to less than ⅛%. Blood pressure had fallen to 180.

April 17, 1902. *Urine* normal in color; alkaline; 1,010. Total, 50 oz. Albumen, large trace. Sediment slight, chiefly pus. Some round cells, and few normal blood corpuscles. Some hyaline casts, with renal cells, and little fat adherent. Few highly refractile casts.

May 5, 1902. *Urine* twenty-four-hour amount 53 oz. Albumen, ⅛%; 1,004; no casts seen.

No convulsions, mind perfectly clear, up in chair; died suddenly May 12, 1902.

Autopsy.— Heart hypertrophied, adherent to pericardium. Valves free from deformity. Coronary arteries show some sclerosis. Kidneys, weight of both, 280 gms. Each is invested in fairly abundant perinephritic fat, which, upon dissection, shows nothing abnormal. Each is invested also in a capsule rather lightly adherent to a surface marked by coarse granular elevations interspersed with deeper, more extensive depressions. The elevations themselves, smooth and of the normal kidney color. No vascular attachments of the capsule to the kidney are apparent. Upon section, markings fairly distinct, cortex $\frac{6}{10}$ cm. in thickness. Glomeruli faintly visible. Pyramids dark, bluish and red.

Cortex marked by radial red lines. Consistence tough.

Microscopically there were no blood vessels between the kidney and the capsule. The arterioles show arterio-sclerosis. The veins and capillaries are injected. There was an organized pneumonia and edema and congestion of the lungs.

Case V. Margaret L. C., twenty-three years old.

Etiology. — In doubt. With the exception of pneumonia at six, well until present illness began.

Present illness began two and a half months ago, with swelling of ankles at night. Seven months later the swelling became general and she was very uncomfortable and short of breath. There was no headache, dyspepsia, pain or impairment of vision. The edema never entirely went, but at times was confined to the legs. Ten months ago she had pneumonia and has been very susceptible to "colds" since. Thinks she has been very much better in the last few months. She lies about the house, and occasionally goes to the theatre or for a short walk.

Examination. — Patient was fairly well developed and nourished. She was pale and had some edema about the eyelids. There was considerable edema of the lower part of the back. Heart apex in fifth interspace in the nipple line. Aortic second accentuated. No murmur. Pulse regular, good volume, rather high tension. Lungs normal. Slight dullness in flanks. *Urine.* Typical of chronic diffuse nephritis. Twenty-four-hour amount at entrance 50 oz. and slightly less

at discharge. Average amount normal. Urea varied from 10 to 40 gm.; average amount normal.

Dec. 6, pale, acid, 1,012, 1-10 % albumen. Many hyaline and finely granular casts, with many fat drops and some fatty renal cells adherent. Rare fatty cast. Urea 16.77 gm.

Operation. — By Dr. S. J. Mixter; Dec. 7, 1902, the left kidney was decapsulated. The capsule stripped easily. The kidney was enlarged and covered with yellow granules. A piece of the kidney was removed for examination and reported by Dr. J. H. Wright to be typical of subacute glomerulo-nephritis. As the patient's condition was not good the second kidney was not operated upon until Dec. 20, when the same operation was performed. The kidney was smaller than the right one and had a depressed scar on one side. The capsule stripped easily. The yellow granules were again present.

Subsequent history. — She did well as far as the operation was concerned and was discharged not relieved Jan. 3, 1903. The amount of urine and urea were both less than at entrance. Oct. 19, 1903, her sister reported that she had been much better since her operation. Edema was less, she had a better color, and was stronger. She went about daily. The urine a month ago showed 1-10% albumen. No blood or pus, but still some casts.

CASE VI. George R. R.

Etiology. — Has had asthma most of his life; has had bronchitis, varioloid and children's diseases.

Three years ago had "kidney trouble" and was laid up nine weeks; recovered and had another attack June, 1901.

Examination showed a pale fat man, but fairly well nourished. Lungs showed the physical signs of asthma. Abdomen distended, with dullness over the dependent portions.

Operation. — In November, 1902, Dr. E. A. Pease decapsulated both kidneys. Has been tapped repeatedly and from four to five quarts of fluid removed at times.

Oct. 30, 1903. Dr. Sawyer reports that the patient is in fairly good condition. An examination of the urine shows twenty-four-hour amount 55 oz., color light, slightly acid, 1,014, albumen ¼%; sediment considerable, light, flocculent, many casts, hyalin, fine and coarse granular, some with fatty renal cells and minute fat drops adherent, fatty degenerated cells, a little free fat, an occasional blood globule. The patient has carefully measured the twenty-four-hour amount, which averages over 50 oz. The edema has disappeared.

CASE VII. Carl H., thirty-three years old.

Etiology. — Apart from the fact that he is a painter, nothing obtained. Has had attacks of weakness, with swelling of the feet, face and legs since last April.

Examination. — The heart is enlarged, with a systolic murmur at the apex. Pulse regular, good, high tension. *Urine.* Sept. 17, twenty-four-hour amount, 45 oz., acid, 1,014, 1-5% albumen, urea, 88%. Few hyalin casts, with an occasional fatty cell and blood globule adherent, an occasional fatty cast, considerable free fat, few normal and abnormal blood globules.

Operation. — Dr. Mixter decapsulated both kidneys Sept. 19.

Subsequent history. — Recovery was uneventful and he went to the Convalescent Home Oct. 14. The amount of albumin had fallen to a trace on Oct. 3. The sediment had also improved, but on Oct. 14 there were still a few casts, with fat adherent. The amount of urine just after operation fell to 10 oz. but went up again immediately and at discharge was 70 oz. It has not been possible to see the patient as he has gone to Maine. Letters sent to him have not been answered, but a friend who has heard from him says he is very much better and works steadily, but is afraid to come back to Boston for fear of catching cold. January, 1904. Patient reports that he again has edema of legs, etc. Has had to give up work.

CASE VIII. W. H. K., male; thirty-three years old.

Etiology. — With the exception of "grippe" ten years ago, the patient had always been well up to several months before, when he caught cold. Has drunk five to eight glasses of beer a day until within last two months.

Present illness. — His feet, legs, body and face became moderately swollen. He felt dull and weak and his head ached slightly. He vomited occasionally. One month ago gave up work. Just before operation he had no gastric symptoms, but the edema persisted and he had dyspnea and palpatation on exertion. His eyes were normal.

Operation. — Dr. J. W. Elliott decapsulated both kidneys, removing a small piece from one for microscopical examination. This was reported by Dr. Wright to be typical of a sub-acute glomerulo-nephritis. The substance of the kidneys was soft, grayish and friable. The one the piece was removed from was a little larger than normal.

Urine. — Typical of chronic diffuse nephritis. The amount had been about 80 oz. until just before operation, when it fell to 25 oz., rising to 95 the fifth day after operaton. The average was about 80 oz. The urine report April 8 was: Color normal, acid, 1,017, albumen ¼%, no sugar. There were many hyalin and finely granular casts, with renal cells and blood adherent. There were a few casts, with fat adherent. There was considerable normal and abnormal blood. The amount for twenty-four hours was 45 oz.

Subsequent history. — His condition was improved temporarily, but had occasional attacks of headache and vomiting. He grew worse and died early in June.

Autopsy. — The kidneys were found slightly more tightly bound in their position than in normal perinephritic tissue. Each organ was apparently provided with a capsule which appeared to be readily removable but which was very intimately connected with the perinephritic tissue.

CASE IX. Francis H. J., thirteen years old.

Etiology. — Scarlet fever at four years, with edema of face and legs during convalescence. Urine dark and scanty. Symptoms of nephritis were gone in two weeks.

Present illness. — Not strong since scarlet fever. After, had frontal headache and was easily tired. Rare gastric upset. Summer before entrance had an exacerbation of nephritis for a week. Had grown gradually worse since then.

Examination. — His face was puffy and hands slightly cyanotic. There was a systolic murmur. The odor of the breath was slightly urinous; there was some edema of the extremities, and his feet were cold and clammy.

Urine. — April 11, 1,017, ½% albumen. Fine and coarse granular casts, with fat and renal cells adherent. Amount 60 oz.

Operation. — On April 12 Dr. W. A. Brooks, Jr., decapsulated both kidneys. He found the tissues very edematous at operation.

Subsequent history. — Ten days after operation the edema was still marked. From May 3 on, the patient had daily hot air baths for some days. The baths were then given at two-day intervals and then every third day. On May 29, his edema had practically

gone and his general appearance was excellent. He was transferred back to the medical service on June 9. An examination of the urine May 28 showed 1-10% of albumen, a rare hyaline and finely granular cast, blood globules and a few compound granule cells. The amount of urine varied greatly. It was 60 oz. when he came to the surgical service, 30 on the day of operation, 60 on the fourth day and 120 oz. on the twenty-fifth day. Dr. Torbert saw the boy Oct. 15. He has been well since July 15, 1902. Two months ago, his mother says, he had a headache and was slightly edematous about the face and hands. This all went in twenty-four hours. He goes to both day and night school, eats well, and is very active. The scars are firm and there is no pain or tenderness in the kidney region. His tongue was clear and breath sweet.

The urine was examined and was free from albumen and casts. It was pale, acid, 1,013. The urea was 88% in the specimen examined. He gets up two or three times at night to pass water and passes a good amount during the day.

To summarize these cases briefly:

Five have died at periods ranging from five days to two years and two months after operation. One case is probably cured. As the urine has only recently been found free from albumen and casts it is too early to classify it as cured. One case has improved and is still gaining, eleven months after operation. Two cases, a year after operation, show very little if any improvement.

In the nine cases the disease was of the chronic diffuse type. In each case ether was the anesthetic used. In two cases in which there was an autopsy some time after operation it was found that a new capsule had formed not essentially different from the old one. The amount of urine and urea varied within wide limits. It was invariably smaller than usual the day after operation but regained or exceeded the previous amount within a few days.

DECAPSULATION OF THE KIDNEYS.[1]

BY JOSHUA C. HUBBARD, M.D., BOSTON,

Third Assistant Visiting Surgeon, Boston City Hospital; Assistant in Surgery, Harvard University.

CASE I. P. M. Male, forty-two years. Entered the hospital June 3, 1902. He had had measles but no mention was made of scarlet fever. He used alcohol to excess. He had had increased nocturnal micturition for five months. Later edema, anorexia, insomnia, epigastric pain, headache and diarrhea appeared. On entrance there was evidence of fluid in the chest and abdomen. There was edema of the legs, genitals, back, abdominal walls and face. The radial arteries were sclerotic. The urine was smoky neutral, 1,019, albumen ¼%. The sediment contained some normal blood, fine granular and hyaline casts with fat drops and fatty renal cells adherent, some fatty renal cells and compound granule cells and triple phosphate crystals. The urea was 1.82% and the twenty-four-hour amount of urine about 36 oz. He did not improve under medical treatment and was operated upon by Drs. Burrell and Blake on June 14. Ether was the anesthetic. Improvement began immediately after the operation. The edema began to decrease in ten days and was entirely gone in six weeks. The amount of urine increased to 150 oz. He was discharged on Aug. 2. At that time the urine was smoky, 1,012, acid and contained 1-10% albumen. The sediment contained an occasional cast with fat, a few renal cells, leucocytes and blood. He was seen last on Oct. 27, 1903, a year and four months after the operation. He is now free from all symptoms, does not have to rise at night to urinate, has no trouble about doing his work — that of a general man on a summer place. He looks well and has no edema of the ankles. He is still drinking as he chooses. The urine passed shortly after a meal was pale, slightly acid, 1,002, urea ½%, albumen slight trace. Nothing found in the sediment.

CASE II. J. S., female, thirty-nine years old. Patient had been in the City Hospital several times since 1894 for fistula in ano and a tubercular proctitis. In 1894 the urine was normal except for pus in the sediment. She entered the medical wards in July, 1902, with a history of chilly sensations, fever, dyspnea, increased frequency of micturition and edema covering a period of four months. The previous history was negative except for the surgical affections mentioned above and measles. There was no mention of having had scarlet fever. The urine examination was as follows: specific gravity 1,006; twenty-four-hour amount 74 oz., albumen ½%. The sediment contained pus, a few hyaline and fine granular casts, a little free fat, a few small round cells, fatty renal cells and red corpuscles. Examination for tubercle bacilli was negative. The symptoms increased in spite of medical treatment and she was transferred for operation.

She was operated upon by Drs. Munro and Blake on Sept. 12, 1902, under ether anesthesia. Each kidney was stripped of its capsule. The pathological diagnosis of specimens taken at the operation was "marked acute degenerative nephritis, slight amyloid degeneration of glomeruli, slight chronic nephritis."

After the operation the urea increased from 1.13% to 1.64%, but the actual amount diminished from 13.90 gm. to 12.60 gm. The edema disappeared. Two and one half months after operation the urine contained ½ to ½% albumen, considerable pus, hyaline and granular casts, many renal cells and some blood corpuscles. She developed a cough, her strength gradually failed, and there was occasional edema of the face. She died without unconsciousness or uremic symptoms on March 18, 1903, six months after operation. The clinical diagnosis at the time of death was tuberculosis of the apex of the right lung, tubercular ulceration of the rectum, tuberculosis of the kidneys. The latter was justified in spite of the negative findings in relation to the bacillus of tuberculosis in the urine.

CASE III. T. E. D., male, thirty-one years old, entered the hospital July 1, 1902 having had headache, edema and dark colored urine for several days. He remained in the medical wards till September and was then discharged. His history furnished no cause for the nephritis except a moderate use of alcohol. He was admitted to the surgical wards on Sept. 17, the edema having returned after discharge accompanied with pain in the back and increased frequency of micturition. The urine at that time was acid, 1,013, albumen ½%, the sediment contained numerous hyaline and fine granular casts of small diameter with renal cells adherent, considerable blood free and on casts, some fat and many renal cells, occasionally fatty. The twenty-four-hour amount varied from 40 to 60 oz. Urea 14.52 gm.

The operation was done, under ether, Sept. 26, 1902,

[1] Read at the annual meeting of the Suffolk District Medical Society, October 31, 1903.

by Drs. Munro and Blake. The pathological diagnosis from bits of the kidney taken at the operation was "chronic glomerulo-nephritis, so-called parenchymatous." Two weeks after the operation the edema was gone and the patient was discharged one week later. April 24, 1903, the patient reported that he had done heavy work every night till three weeks ago and felt stronger than ever. At that time he began to drink hard and continued this for two weeks when edema of his face reappeared. While he had been drinking, his urine, which had been clear, became the color of bock beer. When seen April 24 he looked well, had slight edema of the ankles, had gained twenty pounds. The urine was smoky, acid, 1,005, albumen ¼% urea .88%. The sediment contained normal blood, a few leucocytes, some renal cells with fat adherent, an occasional compound granule cell and a very few hyaline and fine granular casts. I have made unsuccessful attempts to find this patient this fall and therefore am unable to give his present condition.

CASE IV. Male, twenty-six years old, entered the hospital Jan. 13, 1903. As a child he had had measles, scarlet fever and whooping cough. Eight years before entrance he had had pneumonia. For six months he had had malaise and indigestion and for four days backache, edema of ankles and dark colored urine. There was general edema and râles over the entire chest, the heart being negative. The urine was high, acid, 1,029, albumen ¼%. The sediment contained many casts, hyaline and fine granular, with small round cells, blood corpuscles, leucocytes and renal cells adherent, a little fat and a few abnormal red cells. He had albuminuric retinitis. The twenty-four hour amount was usually in the neighborhood of 30 oz. His symptoms grew worse and the edema increased under treatment.

Operation under ether Jan. 30, 1903, by Drs. Burrell and Munro. He was in poor condition during and after the operation. Pathological diagnosis from bits of the tissue taken at the time of the operation, "subacute glomerular (amyloid) nephritis." The urine after operation did not change except for the appearance of some red blood corpuscles. On the second day he passed 14 and on the third 20 oz. He was conscious. He vomited for twelve hours on the third day. The vomiting was finally stopped by some spirits of chloroform. He then retained milk and lime water. He lost strength and finally died, without signs of uremia, on Feb. 4, five days after operation.

CASE V. Male, twenty-nine years old, entered the hospital Nov. 19, 1902. He used alcohol to excess. For two weeks he had had chilly sensations, fever, slight cough, headache, nausea and vomiting, edema, a scanty and high colored urine, and diarrhea. The urine was smoky, acid, 1,026, albumen ⅛%. The sediment contained very many casts, hyaline and granular, with renal cells, fat drops and blood globules adherent; few squamous epithelium cells, neck of bladder, small round cells leucocytes and red corpuscle. Urea varied from 2% to 7-10% and the twenty-four-hour amount of urine from 20 to 50 oz. He did not improve after more than two months of medical treatment. At that time the urine was practically unchanged and there were evidences of fluid in both pleural cavities and the abdomen. He had albuminuric retinitis. Operation under ether Jan. 27, 1903, by Drs. Burrell and Munro. The pathological diagnosis from specimens removed at the time of the operation was "subacute glomerular nephritis." After the operation the amount of urine dimished at first and then increased and the edema decreased somewhat. Five weeks after the operation he developed a bronchopneumonia from which he nearly died. On April 14, almost three months after operation, he still had considable edema. The urine at that time was pale; acid, 1,020, albumen ½%; urea 1.70% with a total of 18.87 gm. The sediment contained many fatty granular renal cells, normal and abnormal blood, fine granular casts of large diameter, with epithelial cells, fat drops and blood adherent; a few hyaline, epithelial and fatty casts. He was discharged to Tewksbury, where he died June 30, 1903, five months after operation. During his stay there he had general edema, a urine loaded with albumen and casts, and cardiac murmurs.

CASE VI. N. D., female, twenty-six years old, had a history of nephritis of six years' standing. An attack of influenza preceded her first symptoms. She entered the hospital first in 1897. The diagnosis of chronic diffuse nephritis was made. She came in again on Jan. 31, 1903. She had had numerous attacks of malaise, muscular weakness, frequent headache, backache, dyspena, epigastric pain, nausea and vomiting. frequent micturition. The urine was pale, slightly acid, 1,012, albumen ¼%, few hyaline and fine granular casts with some fat and renal cells adherent, numerous squamous cells and leucocyte, single and in clumps, many small round cells, rarely a normal blood globule. The twenty-four-hour amount varied considerably up to 54 oz. and the albumen up to ¼ %. The physical examination was, in brief, an enlarged heart with accentuation of the second sounds, edema of the eyelids and extremities and a foul breath. The urine collected by segregation from each kidney gave similar results.

As there had been no material gain she was operated upon on March 7, 1903, by Drs. Thorndike and Faulkner. The kidneys were four inches long, contracted anteroposteriorly. Decapsulation left a granular surface which bled but little. The pathological diagnosis from a specimen removed was "chronic glomerulo-nephritis." After operation she steadily failed, had headache and vomiting and a decrease in the total amount of urine secreted and died two days later.

CASE VII. Boy nine and a half years old. He had had measles, diphtheria and typhoid, but not scarlet fever. He entered the Children's Hospital Sept. 11, 1902. His symptoms were nausea, vomiting, dyspnea and edema. The urine was smoky, acid, 1,010, albumen ¼ to ½%. The sediment contained many hyaline and granular casts, with blood and renal cells adherent, few fatty and epithelial casts, many round cells, often fatty, leucocytes free and in clumps, a few decolorized red corpuscles and a few squamous epithelial cells, considerable free fat. The twenty-four-hour amount of urine was ordinarily between 400 and 800 cc. and the urea between 5 and 10 gm. He developed considerable edema and ascites which required tapping three times. On Dec. 2 he was transferred to the surgical service with edema of face, back, external genitals and lower extremities. The heart was enlarged and its action irregular. There was evidences of fluid in the pleural cavities and abdomen. The total twenty-four-hour amount of urine was decreasing and the general condition was growing worse.

Jan. 1, 1903, he was operated upon by Dr. Cushing. Anesthesia was produced by nitrous oxide and ether. The kidneys were enlarged, the capsules not adherent. The denuded surface was matted with yellowish white areas, alternating with injected ones. The cortex was quite friable. No cicatricial depressions of the surface were noted. After the operation the headache and nausea disappeared and the edema began to diminish, and by the eighth or ninth day had disappeared entirely except in the legs. The twenty-four-hour amount of

urine increased to 1,170 cc. and the urea on the seventh day was 11.20 gm. The albumen and sediment were less. After the eighth or ninth day the boy began to grow worse, the temperature was elevated, the wounds were opened by the returning edema, the amount of urine and of urea both diminished and the nausea and vomiting recurred. The boy died Jan. 19, nineteen days after operation, with the symptoms of acute pulmonary edema and cardiac exhaustion.

This makes a series of seven cases.[1] None of them can be said to have been cured, as not one of them has a urine free from albumen. One is, however, without subjective symptoms or a urinary sediment a year and four months after operation, and another seven months after operation, though lost sight of since. Of the remaining five, one, somewhat improved, died six months after operation, of tuberculosis. The remaining four died, unimproved, two and nineteen days and one and three months after operation. Looking over these cases one cannot find any apparent reason, either in etiology, duration of the disease, or findings at the operation, why one patient should survive and be greatly benefited, another survive but the progress of the disease be not arrested, and a third die within a few days.

Such cases as the first one reported are certainly brilliant, and possibly such a one differs in some respect at present undiscovered from those that die.

In regard to the case who has still albumen but no casts in the urine, Edebohls says that the albumen may presist for some time after the casts have entirely disappeard in the cases that are eventually to be cured.

Medical Progress.

RECENT PROGRESS IN GENITO-URINARY SURGERY.

BY F. S. WATSON, M.D., AND PAUL THORNDIKE, M.D.

GENITO-URINARY TUBERCULOSIS.

Baumgarten[1] says that he is unable to start a tuberculous process in a testicle by injecting tuberculous material into the urethra, although he could infect the deep urethra, prostate, and bladder in this way. He claims that tubercle bacilli never travel against the current of either secretory or excretory fluids, and explains his results in this way.

Kraemer[2] agrees with Baumgarten and so asserts that tuberculous infection of the testicle is impossible from coitus.

Delli Santi,[3] on the other hand, was able to start tuberculous epididymitis in dogs by introducing bacilli into the urethra. He thinks this investigation establishes the possibility of contagion from tuberculous lesions in the female genital organs.

Hausen[4] found it impossible to induce hematogenic tuberculosis of the genito-urinary organs in his experiments on rabbits, even when he made subcutaneous injections of tubercle bacilli coincident with the introduction of bacilli into the blood.

Bürgner[5] reports success with his method of high castration for tuberculosis. He frees the vas as high up as possible and then pulls on it until it breaks. In this way about 4-5 cm. can usually be removed. When he thinks that seminal vesicle and prostate are also involved, he injects a 10% glycerine solution of iodoform upward through the vas as a preliminary step to castration.

INOSCOPY.

E. J. Masselin[6] agrees with Jousset that inoscopy reveals tubercle bacilli in organic fluids in which they are difficult or impossible to demonstrate by other means. The bacteria become entangled in the fibrin of organic fluids, and by disolving of the fibrin with a pepsin digestive mixture the organisms can be set free and then are readily centrifuged for examination.

OPERATIVE TREATMENT OF CHRONIC BRIGHT'S DISEASE.

R. Guiteras[7] gives a carefully prepared and extensive tabulation of reported cases and concludes as follows:

(1) Chronic nephritis should not be operated on until medical treatment has proved of no avail.

(2) The time for operation is when it is noticed that the process is advancing rapidly and we fear that the heart will soon become overtaxed.

(3) The operation for chronic Bright's disease which has proved least dangerous and which has shown the best results, is nephropexy performed on a single movable kidney.

(4) The most unfavorable cases for operation are those of diffuse nephritis.

(5) Cases of general anasarca with bad heart action should not be operated on; if the heart action is good an operation performed as a *dernier ressort* may give the patients a few extra months of life, provided they survive it.

(6) Where there has been a marked destructive process in the kidneys, as a result of a nephritis, the operation may relieve them for a number of weeks or months, but they generally fail again and die when the new capsule begins to contract.

HYPERNEPHROMA.

P. Thorndike and J. H. Cunningham, Jr.[8] report three cases of these tumors of adrenal origin with pathological reports. The tumors cannot be classified as carcomata, carcinomata,

[1] Cases I, II, III, IV, V, were also reported in Boston Med. and Surg. Journ., Aug. 13, 1903; Case VII was also reported in Archiv. of Pediat., August, 1903.

[1] Archiv. f. Klin. Chir., 1901, Band. lxiii.
[2] Deut. Zeit. f. Chir., Leipsic, lxix., No. 2-4.
[3] Riforma Medica, Palermo, xix, No. 28.
[4] Annales d. Mal. d. Org. Genito-Urinaires, Paris, 1904, p. 408.
[5] Beitrage z. Klin. Chir., Tübingen, 1903, p. 342.

[7] N. Y. Medical Journal, Nov. 14, 1903.
[8] Boston Medical and Surgical Journal, Dec. 3, 1903.

etc., as they are of adrenal origin and do not conform to any one class of growth. They grow rapidly, are usually malignant (though occasionally benign) and metastases form through the blood current, most frequently in the lungs, liver and bones. Plates accompany the article, illustrating characteristic points in gross and microscopic pathology. The affected kidney is generally large, with a nodular surface, but retains the general outline of the organ. On section the tumor tissue is yellowish, with a firm and distinct stroma. Some nodules show areas of hemorrhage and degeneration.

E. Bohler [9] collected 39 cases of hypernephroma. Of the 36 cases in which the age was determined only 4 were under forty years, 5 were forty to fifty years, 24 were fifty to seventy years, 3 were over seventy years. The disease occurred 19 times in men and 18 in women. Right kidney was affected in 16 cases and left in 20 cases.

PERIRENAL FAT.

W. W. Keen [10] says there are two distinct layers of fat surrounding the kidney. One he calls the transversalis layer and the other the proper perinepheric fat. These layers are separated by connective tissue and there is a very distinct interval between them. Walkow and Deletzin in 1899, Gerota in 1895, and Zuckerkandl in 1883, describe a similar condition.

THE PATHOGENESIS AND PATHOLOGICAL ANATOMY OF ENLARGED PROSTATE.

L. R. G. Crandon [11] gives the results of a study of 37 prostates, 12 of which were enlarged, 24 normal in size and 1 small. He discusses his findings with great care and draws conclusions as follows:

(1) The underlying cause of the usual form of prostatic enlargement and of certain forms of prostatic atrophy is a slow formation of new connective tissue due to infection, or to infection aggravating a senile degenerative process.

(2) The gonococcus is probably most often the specific infection.

(3) Neoplasms, fibronyomata and adenomata occur, but may be called rare.

THE PROSTATIC SECRETION.

Stern [12] analyses this secretion and mentions a special enzyme which it contains, and says: It is as yet impossible to demonstrate the importance of this fluid. He assumes that it is important in overcoming the quiescence of spermatozoa and also in promoting a state of osmosis essential to fecundation.

GONORRHEAL EPIDIDYMITIS.

Baermann [13] asserts that epididymitis occuring during a gonorrheal urethritis is due to local invasion of gonococci which can be demonstrated in fluid drawn off by puncture and that sometimes it is possible to find gonococci persisting for years in the relics of an old epididymitis.

NEW OPERATIONS.

A. D. Bevan [14] describes an operation for undescended testicle, and illustrates the steps of the procedure with a series of cuts. He believes that all testes which can be palpated should be transplanted into the scrotum. He operates through an incision made over the inguinal canal, but not carried down over the cord and into the scrotum. He opens the peritoneum, ties it off as in hernia operations, making a tunica for the testis out of the vaginal portion of peritoneum, and then frees the cord from all its adhesions so carefully that it can be dropped into the scrotal pocket and lie there with no tension upon it.

E. Reynolds [15] describes an operation of nephroureterectomy which he performs. He operates through a four-inch incision, and is able by posture to obtain gravity dilatation of the wound so that the wound cavity, if the posture has been well taken, " opens widely and can be inspected throughout as easily as if it were a surface wound."

Reports of Societies.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

PROCEEDINGS OF THE SIXTEENTH ANNUAL MEETING, HELD AT THE PIEDMONT HOTEL, ATLANTA, GA., DEC. 15, 16 AND 17, 1903.

(Continued from No. 3. p. 72.)

SPURIOUS DYSMENORRHEA.

DR. HENRY T. BYFORD, Chicago, made a plea for a more rational treatment of dysmenorrhea. After naming twenty-five varieties that had been mentioned in textbooks, the author called attention to their disappearance therefrom. Many supposed cases were spurious in character. These had been perpetuated by the physician and cured by the quack.

The absurdity of the nasal cure was emphasized and the cures referred to as spurious. Instances of menstruation in the male were quoted.

The trend of the paper was to condemn writers for bringing the symptom into the foreground when it should be kept in the background, and for wasting their own time and that of their readers in ridiculous refinements and speculation.

MEMORIAL ADDRESS ON DR. W. E. B. DAVIS.

DR. RICHARD DOUGLAS, Nashville, Tenn., spoke impressively of the work that had been done by Dr. Davis, and pointed out in a masterly way the distinguishing characteristics of the deceased.

DIAGNOSIS AND TREATMENT OF CONGENITAL MISPLACEMENT OF THE HIP IN INFANCY.

DR. ALBERT H. FREIBERG, Cincinnati, Ohio, had been able to ascertain that in several cases children with congenital misplacement of the hip had been late in walking. It was a common experience in mild grades of rachitis that children were late in walking. The usual age of sixteen months was passed by, and the rachitic child not only failed to walk, but was usually also unwilling to stand. The author had been able to ascertain in several cases, and to observe in one, that children with congenital luxation stood readily at the usual age for walking, and especially if allowed to support themselves by holding on to some object. It was only when independent effort at locomotion was urged that the child showed its timidty and refused to make the attempt as a normal child would. This period was gone through by every normal child, but in some cases its long continuance might be attributed to congenital luxation. The length of this period in luxation cases varied greatly, but in every case was finally determined by the child's learning to walk with more or less limping, at which time the diagnosis was usually made and was of no further interest in this connection. In some few instances mothers observed these things and possibly also that the apparent breadth of pelvis and perineum was unusually great. It was therefore urged that in the presence of any of these signs which had been referred to, attention be paid to the possibility of congenital luxation, and that in the event of any doubt the x-ray be resorted to as a final means of precision.

Experience had abundantly shown the feasibility of operative procedure after the age of one year, and that the results amply justified the great additional care which was necessary to prevent the dressings from becoming soiled in so young a patient.

THE PROGRESS OF URETERAL SURGERY.

DR. J. WESLEY BOVEE, Washington, D. C., President of the Association, selected this title for his presidential address. After referring to the deaths of Drs. W. E. B. Davis, George J. Engelmann and J. McFadden Gaston, he confined his remarks to the surgery of the ureter, giving its history and present status.

The treatment of ureteral calculi first claimed attention since the diagnosis and treatment of this condition were very much studied at the present time. The use of the x-ray was the simplest procedure known for purposes of diagnosis, and were it accessible at all times, and completely reliable, no other method would be comparatively valuable. Unfortunately, such conditions as calculous anuria might render a patient in a secluded place so ill that this method of investigation was necessarily precluded. Moreover, calculi might be of sufficient size to block the ureter and give no shadow in the radiograph. For this reason especially other plans of examination should be employed, although the necessity of constant manipulation of the ureter was a *sine qua non* to dexterity in treating other conditions of this structure. Palpation would ever have its important position. Exploration was an important method in such investigations. Tubular calculi might escape discovery by this plan. The wax-tipped bougie, suggested and used by Kelly, was especially sensitive, and no doubt if it touched a calculus it would receive a telltale impression.

In the treatment of ureteral calculi the proper plan was extraperitoneal uretero-lithotomy, as infective urine was usually associated with this condition, and easily produced peritonitis if permitted to come in contact with the peritoneum. If pus was not present, the establishment of uretero-cutaneous fistula would seldom be necessary, though careful drainage of the wound would be advisable. This rule applied to every part of the duct. He was firmly convinced the ureteral wound should be made longitudinally whenever possible, and sutured after lithotomy. If much necrosis of the ureter was manifest, as had often resulted from the impaction of a calculus, each case should be treated according to the judgment of the surgeon, and such modifications as resection or exsection, with uretero-ureteral anastomosis or uretero-cystostomy might rarely be required. Frequently pyonephrosis accompanied calculous ureteritis. Incision and drainage, and probably nephrolithotomy would be needed in addition. The routes employed depended upon the location of the calculus, the bladder, the vagina, or loin being selected. He could only endorse the rectal route, as employed by Ceci, when examination revealed a calculus ulcerating into the rectum or threatening to do so.

For ureteral fistula nothing need be done unless obstruction of the duct below the fistulous opening existed. In such a case the caliber of the canal must be restored. Usually the fistula would then close spontaneously, although so much cicatricial tissue might be deposited about the opening as to prevent closure. Suture, or perhaps resection, might be required in that case.

Dr. Bovee referred to subcutaneous injury of the ureter, saying that no treatment was advisable unless evidence of extravasation of urine or of ureteral obstruction existed. For partial division of the ureter suturing should be applicable. Abnormal ureteral terminations of congenital origin might be corrected by uretero-cystostomy, usually by the vaginal route. Fortunately, in these cases the ureter was abnormally long, and therefore the difficulty was much less than was the same operation for other indications. The ureter might be removed in whole or in part for tumors, tuberculosis, and malignant disease. In 1899 he was able to collect from literature about twenty-four cases of partial or complete ureterectomy. Now the number had increased to nearly one hundred. In complete ureterectomy or nephro-ureterectomy in women probably the loin and vaginal incisions

constituted the best plan. In his last case he separated the lower two inches through a vaginal incision, and then separated and withdrew the kidney and ureter by the loin route. This he believed to be the best of all.

For ureteritis the treatment had been largely of irrigation and topical applications. He had been disappointed in this work, and had grave doubts of its being the best. Probably the violence done to the lower part of the ureter by this instrumentation counterbalanced the benefits. He had had a few cases of trigonitis that had come to him after ureteral irrigations were said to have been made. He had, in consequence, been led to speculate as to whether a non-alcoholic, non-nitrogenous diet, with diuretics and rest in bed, might not be superior treatment for simple ureteritis.

PUS COLLECTIONS IN THE PELVIS.

DR. C. N. CHAVIGNY, New Orleans, La., discussed this subject, in which he reported three cases.

THE TECHNIQUE OF THE VAGINAL METHOD.

DR. J. RIDDLE GOFFE, New York, said in his own hands the scope of the operation, namely, the conditions to which the vaginal method was applicable, was steadily widening. It was no longer confined, on the one hand, to simple puncture and drainage, nor limited, on the other, to the radical operation of hysterectomy. All the intermediate procedures that were called for by the multifarious pathological conditions found in a woman's pelvis found their most direct route through the vagina.

There were two vaginal incisions through which the pelvic cavity could be reached; one, posterior to the cervix into Douglas' pouch, and the other anterior to the cervix, separating the bladder from the uterus and opening up to view and touch the entire contents of the pelvis. The latter was the one which afforded the greater facilities for operative procedures, and the one which he depended upon almost exclusively. The posterior incision was frequently used in connection with it, to afford additional opportunity for the purpose simply of securing drainage and in some cases for manipulation. The procedure was described.

The simplest application of the vaginal method, and the one that probably commended itself most universally to the profession, was incision and drainage of pelvic abscesses.

The author's cases had embraced every variety of disease from simple retroversion, with or without adhesions, to prolapsed and cystic ovaries, unilateral and bilateral salpingitis, ectopic gestation, fibroid tumors of the uterus, and dermoid cysts. The method lent itself to every form of conservative work upon the uterus and its appendages that had been suggested in the trend of recent modern gynecology. The successful application of it required patience, experience and skill, but when once the profession had been convinced of its superiority, he believed it would steadily and rapidly grow in favor and become the accepted method for the man who practiced the specialty of gynecology.

TUBERCULAR OSTITIS OF THE KNEE.

DR. A. R. SHANDS, Washington, D. C., said that the management of a case of white swelling could be embraced in the terms immobilization and protection in any and all stages of disease. The indication was to preserve the function of the joint as far as possible, to arrest the progress of the disease, to prevent and correct deformities. Immobilization and protection with the best hygienic surroundings and the best tonic treatment appropriate to the individual case would best accomplish the indication just mentioned. If the diagnosis was made early and this line of treatment faithfully carried out, a large percentage of cases would yield very favorable results, many recovering with little or no disability. When it became necessary to incise and drain a joint, it should be done thoroughly and good drainage should be kept up just as long as there was any discharge. When the infection of the joint was due to an ostitis that was near the surface of the ends of the bone, often the diseased bone sloughed away, and when it could be easily located and curetted, most excellent results were obtained. A case was cited in point.

Excision of the knee should never be done in children except in extreme cases, and even then the author believed that amputation would be best, for an artificial leg was more useful than such a leg as a child would have after excision.

BILATERAL DIFFUSE VIRGINAL HYPERTROPHY OF THE BREASTS.

DR. GEO. BEN JOHNSON, Richmond, Va., reported the case of a white girl, aged sixteen, four feet, ten inches high, weighing one hundred and twelve pounds, who had this disease. The breasts hung from the chest wall at about the fourth rib and reached to a point just above the symphysis pubis. The nipple was flattened and stretched. The substance was soft and of similar consistence to that of a well-nourished multipara's breast; the glandular masses scattered throughout were distinctly palpable. The breasts were almost symmetrical, with the exception of a lobular division at the base of the left breast of the same general structure as the main tumor. Two small scars near the right nipple indicated the site of former abscesses. The anteroposterior circumference of the left breast was 19¼ inches; the anteroposterior circumference of the right breast was 21¼ inches; the superior inferior circumference of the left breast was 32 inches; and of the right, 31 inches. Operation was performed under ether anesthesia, and occupied thirty-five minutes, the left breast being removed first, followed immediately by the removal of the right. The breast was held above the field of operation, and the amputation carried on as rapidly as the vessels could be caught by assistants. Healing was by primary intention, and the patient was up and about in six days.

DR. GEORGE H. NOBLE, Atlanta, Ga., reported a case of excision of the psoas magnus muscle for sarcoma.

THE DIFFERENTIAL DIAGNOSIS OF SYPHILIS AND CANCER OF THE VULVA.

DR. BARTON COOKE HIRST, Philadelphia, read a paper on this subject. After referring to the differential diagnosis of these two affections, he reported the case of a woman, twenty-eight years of age, single, who had never been pregnant. She denied ever having led an immoral life, and the possibility of venereal infection. Ten years ago she was operated on for hemorrhage and fissure *in ano*. The wound of the operation did not heal properly. More than a year ago the patient noticed an ulcerated condition of the vulva, and a short time afterward incontinence of feces, followed soon by incontinence of urine. For two years past there had been amenorrhea. On making a specular and digital examination a fistula between the fossa navicularis and the rectum was discovered. The whole urethra was gone; there were three little tubercles at the neck of the bladder, these being all that was left of it. The vagina above the neck of the bladder was perfectly healthy. The cervix was normal except that it was atrophic, as was the whole uterus. The case, at first sight, looked like an inoperable epithelioma of the vulva. It was so pronounced by one of the most experienced dermatologists in Philadelphia. But there was none of that extensive infiltration and elevation of the skin surface around the edges of the ulceration, such as was seen in an example of extensive epithelioma of the vulva, considerably advanced, but not yet inoperable. Moreover, numerous pieces of tissue from different places in the ulcerated area showed nothing characteristic of cancer. There was everywhere the most extensive round-cell infiltration and necrosis of tissue. The microscopic study, as well as the macroscopic appearance suggested syphilis in the ulcerated gummatous form as the most likely possibility, epithelioma being excluded.

Accordingly, the patient was put on specific treatment in spite of her negative history, and the entire absence anywhere upon her body of signs indicating an old syphilitic infection. The treatment was given up within a week, as the patient was severely ptyalized and could not endure large doses of potassium iodide. Lupus next suggested itself. On two separate occasions, under anesthesia, twelve or fifteen pieces of diseased tissue were removed for microscopical examination. No tubercles nor bacilli could be discovered anywhere. Inoculations in animals were negative. The urine contained no tubercle bacilli. The bladder itself was healthy. There was a response to the tuberculin test, but the woman had a patch of consolidation in the apex of one lung. Meanwhile the patient was given x-ray treatments every other day for eight to ten minutes. Within three weeks the external ulceration was healed. The local appearance at that time showed great improvement. Two weeks later the rectovaginal fistula spontaneously closed under the continuance of the x-ray applications. Nothing remained of the original disease except the absence of the urethra and an elephantiasic condition of the labia majora. The former had been corrected by urethroplasty. The speaker had not yet joined the new urethra to the opening in the bladder, so that the establishment of continence of urine was still doubtful but he was quite hopeful of making the patient eventually entirely comfortable.

(To be continued.)

Recent Literature.

Atlas of External Diseases of the Eye. By Prof. O. HAAB. Second edition, revised. Edited by G. E. DE SCHWEINITZ, A.M., M.D. W. B. Saunders & Co. Philadelphia, New York, London. 1903.

This companion book to Haab's "Atlas of Ophthalmoscopy" which is now passing through its second edition has been thoroughly revised by the author and re-edited with certain additions by Dr. De Schweinitz. Although it has not been attempted in the translation to follow the original text with undue accuracy it has been nevertheless the desire of the editor to convey with faithfulness the real meaning of the author. With few exceptions the excellent series of plates which illustrates the text has been painted from nature and in the chromo-lithographic reproduction difficulties in color have been surmounted with cleverness and ingenuity. The brief treatise on ocular pathology and treatment taken in connection with the series of plates and the clinical history which accompanies each of them, form a manual which will be appreciated alike by the practicing physician and student.

Wathen's Epitome of Histology. A Manual for Students and Physicians. By JOHN R. WATHEN, A.M., M.D., Professor of Surgery, etc., formerly Professor of Histology and Pathology, Kentucky School of Medicine, Louisville, Ky. 12mo., 220 pages, 114 illustrations. Cloth. Lea Brothers & Co., Publishers. Philadelphia and New York. 1903.

This little book is intended to assist a student to pass an examination in histology without really knowing the subject. In case of an examination in which the test is the recitation by the student of a certain number of words learned more or less by rote the book might help — but it is to be hoped that there are no such examinations still extant. The volume contains a large number of erroneous statements, but is clearly and succinctly written. The illustrations, which are almost entirely borrowed from various textbooks by well-known histologists are, though badly printed, essentially good. We have noted nothing else in the book deserving praise.

Clinical Talks on Surgery. By JAMES G. MUMFORD, M.D., Assistant Visiting Surgeon to the Massachusetts General Hospital and Instructor in Surgery, Harvard University Medical School. The Old Corner Book Store. Boston. 1903.

Under the above title is presented in book form the methods of clinical instruction of the writer. It represents the results of ten years' experience as a teacher of minor surgery, and the subjects discussed are the "common-place" ones usually briefly treated in the ordinary textbook.

The book is arranged as ten lectures. I. Examination and Study of Cases. II. Incised Wounds. III. Simple Fractures. IV. Lacerated Wounds. V. Compound Fractures. VI. Granulating Wounds and Varicose Ulcers. VII. Felon, Whitlow, Paronychia, Palmar Abcess. VIII. Boils, Carbuncles. IX. Bunions, Ingrowing Nails, Corns and Warts. X. Massage.

It is a very interesting, well-written little book of 115 pages, not illustrated except by its graphic phraseology, full of practical suggestions and is a forcible exposition of the best principles not only of teaching, but also of the theory and practice of surgery. The emphasis is not all placed on operative technique, and the student is not impressed with the idea that the only knowledge necessary for a surgeon is the knowledge of how to operate. It embodies the principles of the best methods of clinical instruction.

We recommend it to the student, for it is full of well-told valuable information. We recommend it to the graduate in medicine for he will read it with interest and, unless he is a "master" in his profession, also with profit.

A Textbook of Diseases of Women. By BARTON COOKE HIRST, M.D., Professor of Obstetrics in the University of Pennsylvania; Gynecologist to the Howard, the Orthopedic, and the Philadelphia Hospitals. 683 pages. 655 illustrations. W. B. Saunders & Co. 1903.

This book is a companion volume to the author's "Textbook of Obstetrics" and embodies an experience of twenty years.

The author adopts the anatomical rather than the pathological classification of the diseases of women. Instead of placing all of the normal anatomy at the beginning of the volume, each chapter is prefaced by a short description of the anatomy of the part treated. This arrangement adds much to the reader's convenience and also to clearness. A chapter on "The Detailed Technic of Gynecic Surgery" is found properly at the end of the book instead of, as commonly, at the beginning. A good feature is an admirable article on coccygodynia, containing a plate showing the injuries and diseases of the cocygeal joints.

The chapter on "Diseases of the Urinary Tract" is hardly up to the high standard of the rest of the work. Here the clearness and conciseness so noticeable elsewhere are lacking. It is doubtful whether a majority of gynecologists would endorse the following statement, page 527: —"No cystoscope is satisfactory that does not carry a light at its distal or intra-vesical end. Hence the cylindrical specula of Pawlik and Kelly, through which the light must be reflected from the exterior, are awkward and inconvenient." Two different electric cystoscopes and an electric urethroscope, also two urinary segregators are advised for the purpose of making diagnosis and treatment.

The illustrations are very numerous, are for the most part original, and are particularly well executed.

It is to be noted that the figures of the injuries and erosions of the cervix in black and white are close after nature and convey a far better idea of these conditions than do the faultily colored plates which are commonly employed. The illustrations of the different forms of mucous polyps of the cervix are remarkably true to life.

The author has given especial attention to diagnosis and treatment throughout the book and has produced a practical treatise which should be of the greatest value to the student, general practitioner and specialist.

A Textbook of Diseases of the Eye. By G. E. De SCHWEINITZ, A.M., M.D. Octavo, pp. 773, 230 text-illustrations and 6 chromo-lithographic plates. Fourth edition. W. B. Saunders & Co. Philadelphia and London. 1903.

That Dr. De Schweinitz's Handbook of Ophthalmic Practice has reached its fourth edition is sufficient evidence of a deserved popularity, and although former editions have been favorably commented upon by this JOURNAL it seems proper at this time to call attention to the fact that the new edition has been "revised, enlarged and entirely reset" and that it will be found to contain many new chapters upon subjects of current interest. A large number of the comparatively newer therapeutic agents are mentioned in connection with descriptions of the diseases in which they are indicated and many of the new text-illustrations and several very finely executed examples of the chromo-lithographic art will be found to be both attractive and interesting.

A Handbook of the Diseases of the Eye. By HENRY R. SWANZY, A.M., M.B., F.R.C.S.I. Eighth edition. P. Blakiston's Son & Co. Philadelphia. 1903.

This Textbook on Diseases of the Eye is passing through its eighth edition and outwardly, at all events, very closely resembles its predecessor, the seventh. While it has gained in illustrations to the number of three it has suffered abridgement in pages to the number of twenty-seven and therefore remains the same compact little volume. Fresh matter has been introduced into some of its chapters and much that is obsolete has been omitted and in this respect the book is improved, but on the other hand an ill-advised conservatism which prevents a too ready acceptance of some of the newer therapeutic agents has doubtless caused the omission of protargol and the more recent argyrol from the very excellent index which accompanies this work.

Textbook of Histology. By DR. PHILIP STÖHR. Fifth American from the tenth German edition. Edited with additions by DR. ALFRED SCHAPER, with 353 illustrations, 850 pp., xvi, 485. Philadelphia: P. Blakiston's Son & Co. 1903.

This admirable book appears in its fifth edition with many minor improvements, bringing the subject-matter up to date. There are also fifty new illustrations and some of the older figures have been withdrawn. The work deserves the great favor it has enjoyed, and certainly occupies the first place among treatises on histology in the English language. It may be recommended not only for students, but as a reference book for practitioners, for whose use it is adapted by the brevity and remarkable clearness of the author's statements. The work is authoritative and singularly free from errors. We hope that in the next edition the author will revise the accounts of spermatogenesis and of the leucocytes, which are at present somewhat inadequate and that he will add descriptions of the parathyroids and of the sinusoids, a class of blood vessels only recently recognized, though of great anatomical importance. The volume is well made, and the publishers have taken much care with the printing of the illustrations, which are beautiful.

An American Textbook of Surgery for Practitioners and Students. By PHINEAS S. CONNER, M.D., FREDERIC S. DENNIS, M.D., WILLIAM W. KEEN, M.D., CHARLES B. NANCREDE, M. D., ROSWELL PARK, M.D., LEWIS S. PILCHER, M.D., NICHOLAS SENN, M.D., FRANCIS J. SHEPHERD, M.D., LEWIS A. STIMSON, M.D., J. COLLINS WARREN, M.D., and J. WILLIAM WHITE, M.D. Edited by WILLIAM W. KEEN, M.D., LL.D., F.R.C.S., (Hon.) and J. WILLIAM WHITE, M.D., PH.D., Fourth edition, thoroughly revised and enlarged. Philadelphia, New York and London; W. B. Saunders & Co. 1903.

We are very glad indeed to see the *American Textbook of Surgery* appear in its fourth edition. It was in danger of being superseded by other books. A great deal of progress has been made in surgery since the first edition of this book, but so far as we can see, the editors have incorporated into this edition all the accepted knowledge. Several new chapters have been added. They are, Military Surgery, Naval Surgery, Tropical Surgery, Examination of the Blood, Immunity and Pancreas. The subject of Acute Osteomyelitis has received special attention in this edition. The treatment of joint disease is not so well considered as it should be. The chapter does not give a clear perspective as to the value of protection and fixation in joint disease. Many of the chapters have been rewritten, notably the chapters on tumors, nerves, joints, etc. In this edition the publishers have used a thinner and a better paper, they have used a smaller type for the new chapters, and yet the book has increased in bulk to 1333 pages. The *American Textbook of Surgery* may be accepted as one of the best textbooks on the subject.

Surgical Diseases of the Abdomen; with special reference to Diagnosis. By RICHARD DOUGLAS, M.D., formerly Professor of Gynecology and Abdominal Surgery, Medical Department, Vanderbilt University, Nashville; Ex-President of the Southern Surgical and Gynecological Association; Fellow of American Association of Obstetricians and Gynecologists; Member of the British Gynecological Association, etc. Illustrated by 20 full-page plates. Philadelphia: P. Blakiston's Son & Co., 1612 Walnut Street. 1903.

This is a large book. Dr. Douglas has been a worker in the special field of abdominal surgery for the past eighteen years and this book is the result of much systematic study on his part and he has relied on his clinical experience to aid him in the choice of subjects. The description of operative technic is not elaborated in this book. The writer has considered it sufficient to indicate the proper surgical procedure and discusses the operative treatment and the after management of abdominal cases. The book is very complete and appended to each subject is an extensive although discriminating bibliography, so that the reader may turn for further information to the original source. The book is very well illustrated, but the paper and printing are not entirely satisfactory. We can recommend the book to any surgeon who is doing abdominal surgery, for it is a capital reference book. Its practical value lies in the fact that the author has had a very large experience and has also a very complete knowledge of the literature of the subject. It is clear, concise and well written. The subject of differential diagnosis is very fully considered.

Nurses' Guide to Surgical Bandaging and Dressings. By WM. JOHNSON SMITH, F. R. C. S., Principal Medical Officer, Seaman's Hospital, Greenwich. Philadelphia: J. B. Lippincott Co. London: The Scientific Press, Limited.

This "vest-pocket" volume ($3\frac{3}{4}$ x $4\frac{1}{4}$ x $\frac{1}{2}$ inches) of 161 pages, bound in brilliant cardinal-red cloth and illustrated by 70 cuts, treats of the details of the aseptic and antiseptic treatment of wounds and other common surgical lesions resulting from traumatism or infection, and of bandaging, splints and apparatus. The data contained as indicated by its title is arranged for the use of nurses. The book is interesting as a review of the subjects treated, or for comparison of the detail of instruction for nurses at Greenwich with that of other hospitals; but as a textbook for the instruction of nurses it deals with the subjects discussed much too cursorily and concisely to be of much value.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JANUARY 28, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published a Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal. 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

27 AND 29 BROMFIELD STREET, BOSTON, MASS

TRYPANOSOMA AND TRYPANOSOMIASIS.

JUDGING from recent investigations, one of the new and comparatively unexplored fields into which medicine is destined to penetrate in the immediate future is that of the protozoa. Evidence is very rapidly accumulating to show that these organisms may produce or be closely associated with certain of the common infectious diseases. In fact, it has long been known that certain types of protozoa are capable of producing disease of great malignancy in animals. In this latter class is to be included an important genus known as Trypanosoma, which in its many varieties produces a considerable number of violent animal infections. In general the disease produced by this organism occurs in epidemic forms in tropical countries, usually with greater severity during the rainy season. There is a period of incubation, followed by fever of varying type. Trypanosoma are found in the circulating blood. The disease progresses with anemia, emaciation, catarrhal conditions, at times falling of hair, and subcutaneous edema, often with ultimate paralysis. The mortality among animals of economic importance is about one hundred per cent. The pathological anatomy of the condition shows the effects of anemia, alterations in the spleen, lymphatic hyperplasia, various infiltrations, enlarged spleen, and fluid in serous cavities. With the clinical course and pathological anatomy the disease presents a perfectly distinct and characteristic type.

The recently published report of the *Biological Laboratory of the Department of the Interior* discusses in great detail this general subject, with special reference to surra as observed in the Philippine Islands. The publication is monographic in its scope, and should prove a valuable addition from an eminently practical, as well as scientific, standpoint of our knowledge of this prominent tropical disease. As in most subjects in which sporadic work has been done for a number of years by various investigators, a somewhat extreme degree of confusion exists in the nomenclature and classification; for example, upwards of eighty names have from time to time been used in different parts of the world to designate the condition of trypanosomiasis.

The first description of the disease appears to date from 1842, from observations made in South America. In 1860 an epidemic which killed thousands of horses occurred in Brazil and Paraguay. In 1858 Livingstone wrote of the tsétsé fly disease, in Africa, which had long been recognized by the natives. In 1880 Evans brought surra into prominence as studied among the natives of India. The loss of animals in India, Africa and South America amounts to many millions of dollars annually. Java and the Philippines have become infected, as well as the Island of Mauritius, the latter since the South African war. In 1902 Manson and others reported cases of the disease in human beings. Smith and Kinyoun published the first report of the infection in the Philippines in 1901, and the conclusion has been reached that the disease undoubtedly was introduced at that time. Curry accurately described the parasite in 1902. Since then the spread of the disease has been phenomenal, and at the present time areas throughout the entire group of islands are infected.

The life cycle of the organism has not yet been worked out with entire satisfaction, but numerous observations have been made which undoubtedly will lead to definite conclusions in the near future. In general the species of Trypanosoma are similar. The body has one chief flagellum and is wound more or less in the form of a spiral, one angle being provided with an undulating membrane. The details of form, however, vary greatly in the same and different species. Limitation of space does not permit us to enter into details regarding the characteristics, the multiplication, the agglutination and the habits in general of these organisms as observed under natural or experimental conditions. For such details we refer our readers to the original report.

Some of the conclusions which the authors of this piece of work, Dr. W. E. Musgrave and Mr. M.

T. Clegg, reached are as follows: The term trypanosomiasis should be used to designate all varieties of the infection as found in different animals; vernacular names, with the exception of surra, should be discarded in most cases. The complete life cycle of the organism is as yet unknown, but it is supposed to occur entirely within the animal economy. Modes of transmission and infection are probably through wounded surfaces in which biting insects, flies and fleas, are the principal agents. The animals serving as hosts for the perpetuation of the disease during the dry season vary in different countries. It is altogether to be doubted whether infection of pastures and water, and the transmission of Trypanosoma through sound mucous membrane is possible. A clinical study of various diseases, among which surra, nagana, dourine and mal de caderas may be mentioned, formerly supposed to be distinct, shows that there is nothing sufficient to differentiate them. The morphological differences of the parasites producing them is not sufficient for classification. Hitherto prophylactic or curative serum has failed to give results, but some hope is entertained from this method of treatment in the future.

Following close upon this exhaustive research is a paper by Novy and McNeal, in the recently published *Journal of Infectious Diseases*, on the cultivation of Trypanosoma brucei. These investigators were able to separate culturally this variety from another and to make various observations of scientific importance. They hope, and the hope is certainly justified, that diseases due to these organisms may soon be subjected to experimental studies, and so indirectly lead to a clear insight into the course of protozoal diseases in general. They are furthermore of the opinion that in spite of present difficulties most of the pathogenic protozoa will soon be cultivated and studied with the same facility as the bacteria.

THE MENSTRUAL FUNCTIONS OF THE MORPHINE HABITUÉ.

Amenorrhea is certainly one of the most constant symptoms of morphinomania in the female and many are the cases which prove conclusively that the menses, which are generally suppressed during the height of the intoxication, make their appearance shortly after a cure of the habit. *A priori*, it would seem difficult that the cachexia of these patients could permit the menstrual function to continue. The nervous system, profoundly depressed, becomes incapable of directing the menstrual function, while the circulatory disturbances, a dilated and weak heart and vascular hypotension, only contribute still more to the general functional wreck of the subject. It would appear that in the first place a dynamic disturbance of a purely vital order is in play, while the anatomical changes arising in the genital organs are simply secondary to a more or less prolonged arrest of the function and to a more advanced intoxication of the system.

Amenorrhea does not necessarily mean that there is an absence of secretion of the ovum, and children have been born of females afflicted by the morphine habit and presenting amenorrhea. On the other hand Levinstein has seen an absolute atrophy of the entire female genital system in a case of morphinomania.

The practitioner should never lose sight of the fact that very often the habit starts from the use of morphine administered during the progress of certain painful affections of the uterus or adnexa. The importance of opium and its derivatives in the treatment of gynecological diseases is well known to all, and it is also proven that as long as the subject is submitted to the constant use of morphine uterine life is momentarily done away with, but it will usually return after the use of the drug has been discontinued.

We know the important part played by the general condition and we also know that all the cachexiæ, such as carcinoma or tuberculosis, are accompanied by a suppression of the menses. It must be admitted, however, that morphine has an elective action upon the glandular structures, on the ovary as on others, such as the breast, salivary glands, the glands of the stomach and intestine. There results, so to say, a sort of inhibitory action, preventing the Graafian follicles from maturing and by reflex action producing a congestion of uterus and ovaries, from which a suppression of ovulation and menstrual flux results.

After a time permanent lesions take place. When an organ atrophies, it loses all its functions and this, as has been said, has been observed in the genital organs of females addicted to the use of morphine.

The reappearance of the menses is considered as a favorable prognostic element as far as the cure of the habit is concerned and apropos of this we would point out an interesting case recorded by Leet, in which a patient after her

cure from the habit had been obtained presented serious nervous symptoms and excitement at each of the menstrual periods. Other such instances have been reported and it consequently is of the greatest importance to note the regularity and progress of the return of the menses, since they indicate that a cure is being effected and also that the patient is not using any deceit.

DIPHTHERIA ANTITOXIN.

WE have received several communications from manufacturers of antitoxin in regard to the statements in the daily press as to the alleged rise in price of anti-diphtheritic serum and the formation of an "antitoxin trust." Chicago seems to be the storm center in regard to this matter.

Accusations against so-called "trusts" are bandied about with extraordinary freedom nowadays. If one desires to give a dog a bad name one immediately calls him a "trust," and enough is said for the satisfaction of the appelant; it is not even necessary to add the adjective wicked, for that seems to be understood in the word "trust."

As to the facts in this matter, they are not easily clear to the disinterested outsider. It seems to be evident that formerly the city of Chicago got its diphtheria antitoxin for much less than the present prices. On the other hand, the manufacturers claim that the serum at present offered on the market is better and stronger, and that the varying scale of discounts and the provision of a device for administration cause that difference to be more apparent than real. The same position is assumed by Eastern manufacturers. We imagine that in this, as in other matters subject to commercial laws, the consumer prefers that open competition between rivals which reduces the price of a product to its lowest terms without regard to the survival of the producer, and the producer prefers some form of combination or agreement which secures a living profit, and if something more handsome so much the better from his point of view. Between the two extremes a happier mean ought to be reached without too much delay, too much friction, and too many hard names — the most opprobious of all of which seems to be the handy term "Trust."

Under existing circumstances it would seem as if Massachusetts had no immediate reason to regret her arrangements for making her own serum.

MEDICAL NOTES.

TYPHOID FEVER AT LEADVILLE, COL. — A very serious epidemic of typhoid is reported from Leadville, Col. About 500 cases of the disease have appeared, and it is believed that the conditions are such that the epidemic will spread. There is also danger that the Arkansas River may become contaminated, which would seriously menace many towns along its banks.

A CENTENARIAN. — It is reported that recently in France a Madame Viguier died at the age of one hundred and seven years. She is said to have lived on milk and dried vegetables, with an occasional small amount of salt pork as a special luxury. French vegetarians are using her as an example of the correctness of their position.

DR. GUY HINSDALE. — At the annual meeting of the Philadelphia Medical Club, held Jan. 16, a loving cup was presented to its retiring secretary, Dr. Guy Hinsdale. Dr. Hinsdale leaves Philadelphia Feb. 1, to take up practice at Hot Springs, Virginia.

DEATH OF AN EXPERIMENTER FROM PLAGUE. — It is reported that the chief of the Bacteriological Laboratory of the Imperial Institute of Experimental Medicine in St. Petersburg has recently died of plague while experimenting with this disease.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Jan. 27, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 46, scarlatina 40, typhoid fever 7, measles 121, smallpox 0.

ANTIVIVISECTION LEGISLATION. — The usual annual petition for the restriction of vivisection is before the Massachusetts Legislature. The bill is said to be essentially the same as that submitted last year and no doubt essentially the same fundamental objections will be brought against its passage.

MEDICAL INSPECTION OF SCHOOLS. — According to the Monthly Bulletin of the Connecticut State Board of Health a recent address by Dr. Lederle brought out the importance of medical inspection of schools. He gave the following incident as the origin of the practice in New York:

A child in a public school was found picking pieces of skin from hands and arm and passing small fragments around to classmates. Some time later all of

these children took scarlet fever, and on investigation it was found that the child had that disease and had been permitted to return to school in the peeling stage, the most dangerous time for the playmates. The incident resulted in the employment of 150 physicians, to visit each public school daily and examine the children. The importance of this step was at once demonstrated. The first year's work showed 108,628 inspections, and 6,839 children excluded for all diseases of an infectious or contagious nature. Later, in 35 schools containing 55,470 pupils, there were found 6,670 cases of contagious diseases of the eyes. During the school year ending June 26, 1903, 71,229 cases of contagious diseases were temporarily suspended from school attendance.

The Decrease of Tuberculosis. — Dr. S. W. Abbott, of the Massachusetts State Board of Health, at a recent address before the American Statistical Association, brought out the important fact that the death rate in New England at the present time is somewhat less than 20 per 10,000 inhabitants, the mortality diminishing from the east coast toward the western portion of the state, and in general the death rate has been less in all New England states. In some a decrease of as much as 50% in the half century. At present fewer deaths occur from this disease among women than among men, which is a reversal of the former rule. Dr. Abbott expresses the hope from these statistics that tuberculosis should be practically eradicated in a comparatively short time.

Overcrowding of Insane Hospitals. — The State Board of Insanity in a portion of its annual report urges again the necessity of providing for the overcrowding of hospitals under its charge. Over 1,700 beds are in use in corridors and day rooms on account of the inadequate facilities of the wards. An added burden has been put upon state institutions also by the law providing for the accommodation at these institutions of the insane inmates of almshouses. It is urged that no time be lost in completing the removal of these patients to the insane hospitals.

Report of the Perkins Institution. — The seventy-second annual report of the trustees of the Perkins Institution for the Blind has been issued as a public document. The somewhat remarkable statement is made that only 18% of all the blind in this state are dependent upon public or private charity. It is maintained that nowhere else in the world, excepting in Saxony, have such results been reached, and that in England, for example, nearly three-fourths of the blind are dependent. In general the financial situation of the institution is satisfactory, but if certain essential improvements in teaching and equipment are to be made, more funds are needed.

New York.

Criticism of Centralization Bill. — A feature of the eleventh annual report on the Insane of the State Charities Aid Association is the severe criticism of what has become known as the Centralization Bill, which provided for the appointment by the State Commission in Lunacy of a treasurer for all the state hospitals for the insane and of a purchasing agent to contract for the supplies for all these institutions. The measure passed both houses of the legislature, but yielding to the universal public sentiment in condemnation of it, the Governor vetoed it. " It was felt," the report says, " that this would completely centralize the financial and business management of the state hospitals, and that, although the vast financial powers already vested in the State Commission of Lunacy were not sufficiently safeguarded, the changes provided for in the bill would remove several of the few remaining restraints upon the exercise of these powers." Regret is expressed at the failure of the legislature to take favorable action on the bill providing for the establishment of a reception hospital for the insane in New York City, by joint action of the state and the city. The establishment of such a psychopathic institution has been urged for years by the Association. It is estimated that accommodations will be needed for 3,300 additional patients in the state hospitals during the coming fiscal year, and the Association recommends that the legislature make provision for at least half that number without delay. A matter of favorable comment in the report is the outings for patients which have been provided by some of the state hospitals. At the Manhattan Hospital on Blackwell's Island, New York, a number of tents were supplied for the patients last summer, and the Rochester Hospital carried out a long-cherished plan by securing a farmhouse on the shore of Lake Ontario, where nearly two hundred patients enjoyed outings.

Pneumonia and its Causes. — At a meeting of the Advisory Board of the Health Department, held Jan. 21, at which among those present were Drs. Janeway, Loomis, Biggs, Derby and Jacobi, an address to the public on " Pneumonia and the Causes Leading up to It," was prepared and given out for publication. The reason for this action is stated as follows: ' The

present increase in pneumonia of various types in New York city is justly a source of solicitude to those having the interest of the public health in charge, for it has now been fully established that a certain proportion of cases of pneumonia are communicable and that by proper care their spread may be prevented." Rerefence having been made to predisposing causes, the manner in which the germs, the immediate excitants of the disease are usually conveyed is spoken of. After urging the importance of a rigorous enforcement of the Department's regulations for the suppression of spitting in unsuitable places, the address goes on to say: " It is furthermore most important that in the cleaning of private houses and all public conveyances and places of assembly the methods adopted should be such as will remove, and not simply stir up, the dust, which when contaminated may incite in susceptible persons some form of acute pneumonia, as well as tuberculosis and the more common colds and catarrhs. Feather dusters should be abandoned, and moist cloths used for dusting. When practicable, sweeping should be done in the evening, so that floating dust may completely settle before its removal by moist cloths in the morning. It should be remembered that dust settles on floors, as well as on furniture, so moist mops should be passed over floors, when these are uncarpeted, as part of the morning dusting. . . . The Advisory Board cordially commends the purpose of the Department to secure proper methods of cleaning and dust disposers in the public schools. . . , and would urge the desirability of instructing in the proper methods of dust disposal all those who have in charge the duty of cleaning public institutions . . . as well as those responsible for factories, stores, offices and the like, and commends the matter to the attention of all householders, to whom, not less than to inmates of public institutions and places of assembly, the risks of dust infections are at this time of especial significance."

A CENTENARIAN. — Felix Carty, a native of Ireland, died in a hospital at Syracuse, N. Y., on Jan. 18, at the reputed age of 104 years.

RAISING THE TUITION FEES AT COLUMBIA UNIVERSITY. — It has been voted by the trustees of Columbia Universityto fix the annual fee for tuition in the Schools of Applied Science and in the College of Physicians and Surgeons at $250 from and after July 1, 1904. The present annual fee in these schools is $200.

OFFICERS OF MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK. — At the annual meeting of the Medical Association of the Greater City of New York, held Jan. 11, the following officers were elected: President, Dr. Thomas E. Satterthwaite; Corresponding and Statistical Secretary, Chairman for the Burough of Queens, Dr. Neil Orrin Fitch; Member of the Executive Council, Dr. Stephen G. Cook. Dr. Augustus D. Ruggles had been renominated for Treasurer, but as his death occurred before the annual meeting, the Executive Council appointed Dr. J. Lee Morrill to serve as Treasurer for the ensuing year.

Obituary.

IN MEMORIAM — WILLIAM INGALLS, M.D.

THE Obstetrical Society of Boston offers the following memorial: " Dr. William Ingalls was an active member of this society for many years, and an honorary member at the time of his death. He attended the meetings regularly and contributed freely to the discussions relating to obstetrics, in which during life he had a very large experience. He had been in attendance at two thousand births, with a mortality of only three mothers on his record.

He served with ability during the Civil War, rising to high rank. He felt with other medical comrades, that the nearer he was to the firing line, the more faithfully he was performing his duty.

To the younger men Dr. Ingalls stood for a type of the old school family physician, who was guide, counsellor, doctor, and life-long friend. Such examples have seemed to be dying out for a time, but they are sure to return again.

Dr. Ingalls had a most attractive personality. We can all recall with love and pleasure the kind refined face, the soft voice, the gentle manner, and the carriage of the well-bred gentleman. He never ceased to win affection; and many of those most devoted to him were among the younger and more brilliant men in the profession. A noble, useful and unostentatious life, ending quietly and peacefully."

A CALM adviser, a gentle friend, precise, punctilious, careful, he gave a long and conscientious service to the hospital. Professional spirit was with him a religion. The Staff of the Boston City Hospital records its appreciation of his just and manly qualities.

D. W. CHEEVER.
J. G. BLAKE.
F. S. WATSON.

Miscellany.

ARTIFICIAL CAMPHOR.

Prior to 1828 chemists made a sharp distinction between organic and inorganic compounds, it being supposed that the latter are capable of preparation in the laboratory, while the former are formed only in the living organism, animal or vegetable, under the influence of a particular force — the life force. This view was rendered untenable by Wohler's discovery that urea, a typical secretion of the animal organism, can be prepared synthetically from cyanic acid and ammonia, two inorganic compounds. Many other "organic" compounds, such as acetic acid, lactic acid, glycerin and sugar have since been made synthetically, and as our knowledge of chemistry increased the old idea about a vital force has lost greatly in significance. We know now that the same chemical forces act both in the organic and inorganic worlds. It is well known that most of the vanilla extract now found on the market is not derived from the vanilla bean, but from coal tar. This coal tar furnishes a large number of other substances which are used in medicine and in the arts. Among these may be mentioned the various analgesics, aniline dyes and perfumes. Indigo and alcohol have also been made from their inorganic constituents, and recently chemists have discovered a method of making camphor synthetically, which makes the manufacture of this substance a profitable industry. Camphor has the formula $C_{16}H_{16}O$, and is an organic compound which was formerly derived only from the camphor-tree *Cinnamomum camphora*, by distilling the chips with water and purifying the product by sublimation. The camphor trees have, however, been growing scarce, and as a result the price of camphor has of late been very high. Japan has a monopoly on the natural product, but this monopoly has now been broken by the manufacture in this country of artificial camphor from turpentine. Turpentine has the formula of $C_{10}H_{16}$ and can be oxidized to $C_{10}H_{16}O$ by heating it with oxalic acid. A ton of turpentine is heated at one time with a quantity of oxalic acid, and out of this mixture is distilled the purest variety of camphor. It takes fifteen hours to complete a lot, and the yield of camphor is 25 to 30% of the weight of turpentine. Various other valuable oils are obtained at the same time as by-products. — *Journal American Medical Association.*

Correspondence.

THE BICYCLE AS A THERAPEUTIC AGENT.

Cleveland, Ohio, Jan. 20, 1904.

Mr. Editor: I was very much interested in the valuable article entitled, "The Bicycle as a Therapeutic Agent," contributed by Dr. L. H. Gulick, and which appeared in the Journal of Jan. 14, 1904.

While reading the article it occurred to me that it might be of interest to relate the use that I have made of the tricycle for the treatment and cure of congenital flat foot or weakened arch in children. When this condition is early observed I recommend the parents to secure for the child a small tricycle, allowing the child to run it about in the house, and also on the sidewalk and street. The results are more certain and satisfactory if the child is kept in bare feet during the warm months. If the vehicle is furnished the child at the beginning of the summer it is not only surprising how much time the tot will spend in the saddle, but better yet, the season often serves to effect a complete cure before the novelty has worn away. This simple measure has been so uniformally successful in relieving the condition that I now never prescribe anything else. It serves the double purpose of taking the weight of the child off the weakened arch, but also is a very potent means of exercising and developing the muscles of the foot and thus gradually but certainly building up a natural resistance to the weakness.

Very truly yours,

Charles J. Aldrich, M.D.

THE EMBRYOLOGICAL COLLECTION OF THE HARVARD MEDICAL SCHOOL.

Harvard Embryological Laboratory,
688 Boylston St., Boston, Jan. 23, 1904.

Mr. Editor: May I have the privilege of appealing through your columns for assistance from practitioners in building up the Embryological Collection of the Harvard Medical School? We are very desirous of obtaining as large a number as possible of human embryos of the first, second and third month, that is, up to about three inches in length, measured from the crown to the breech. For our purposes it is important that the specimens be placed as promptly as possible in a preserving fluid. We recommend as a preservative 10% formalin, that is, ten parts formalin with ninety parts water. This mixture is readily obtainable at any apothecary's and gives good results.

The laboratory will pay all expenses incurred in preserving and forwarding specimens.

The collection comprises at present sixteen series of sections from human embryos. Each series is carefully catalogued, and all the sections in the series are counted, so that any section can be immediately found by its number. The collection also includes to this date 180 series of other mammals, and over 600 series of the lower vertebrates, all representative types. As we have now good sets of series of sections of pig, rabbit and cat embryos, it has become more important than ever to secure a good set of the human series, so that it will afford a complete demonstration of the early development of man. Such a collection is possible, as is shown by the success of Prof. William Reis at Leipzig. Its scientific value can hardly be overestimated. With the generous assistance of practicing physicians the requisite specimens can be secured, and I think that the Laboratory can pledge itself to make the best use of all material received, especially as it has now the great advantage of the services of a workman who has become skilful and reliable in the cutting of serial sections.

The Harvard Embryological Collection is intended primarily as an aid to original research. Its use is by no means restricted to the officers and students of the Laboratory, but on the contrary it is opened freely to all competent investigators, who wish to profit by its advantages. I have the honor to remain,

Yours respectfully,

Charles Segwick Minot.

RECORD OF MORTALITY

Deaths reported, 3,346; under five years of age, 912; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 713, acute lung diseases 770, consumption 370, scarlet fever 34, whooping cough 8, cerebrospinal meningitis 10, smallpox 3, erysipelas 15, puerperal fever 22, measles 31, typhoid fever 50, diarrheal diseases 78, diphtheria and croup 89.

From whooping cough, New York 2, Chicago 1, Pittsburg 2, Lawrence 1, Newburyport 1, Gardner 1. From smallpox, Pittsburg 3. From cerebrospinal meningitis, New York 7, Holyoke, Newton and Medford 1 each. From erysipelas, New York 3, Chicago 6, Baltimore 2, Pittsburg 1, Boston 3.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Jan. 2, the death-rate was 20.6. Deaths reported, 5,944; acute diseases of the respiratory organs (London) 228, whooping cough 135, diphtheria 68, measles 152, smallpox 3, scarlet fever 35.

The death-rate ranged from 11.5 in Kings Norton to 35.1 in York; London 21.1, West Ham 22.0, Brighton 24.9, Southampton 18.0, Plymouth 18.6, Bristol 20.3, Birmingham 23.3, Leicester 18.5, Nottingham 18.9, Liverpool 26.8, Bolton 21.4, Manchester 23 2, Salford 21.0, Bradford 19.3, Leeds 21.3, Hull 18.8, Cardiff 19.6, Rhondda 14.8, Barrow-in-Furnace 16.8, Preston 32.4.

METEOROLOGICAL RECORD.

For the week ending Jan. 16, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING JAN. 23, 1904.

A. M. MOORE, surgeon. Retired, detached from the naval recruiting station, Chicago, and ordered home.

G. B. WILSON, surgeon. Detached from the "Wabash" and ordered to the naval torpedo station, Newport, and to additional duty in attendance upon naval and marine officers.

J. E. GARDNER, surgeon. Ordered to the "Wabash."

G. P. LUMSDEN, surgeon. Detached from the naval torpedo station and ordered to the naval recruiting and marine recruiting stations, Chicago, Ill.

A. R. WENTWORTH, surgeon. Detached from the "Albany" and ordered to the "Solace."

R. P. CRANDALL, surgeon. Detached from the "Wisconsin" and ordered to the "Oregon."

M. S. GUEST, passed assistant surgeon. Detached from the "Oregon" and ordered to the "Albany."

U. R. WEBB, assistant surgeon. Detached from the "Annapolis" and ordered to the naval station, Cavite, P. I.

L. W. BISHOP, assistant surgeon. Detached from the naval hospital, Yokohama, Japan, and ordered to the "Annapolis."

R. K. MCCLANAHAN, assistant surgeon. Ordered to the Asiatic station via steamer sailing from San Francisco, Feb. 1.

RECENT DEATHS.

EDMUND S. HANNA, M.D., a retired physician, died recently at East Orange, N. J., from apoplexy. He was seventy-five years old and a native of Steubenville, Ohio. He was graduated from Jefferson Medical College, Philadelphia, in 1850, and practiced for many years in Pittsburg, where he held the position of surgeon to several institutions and railroad companies. He had resided in East Orange for the last eight years.

J. VARNUM MOTT, M.D., a well-known New York physician and a grandson of Dr. Valentine Mott, died suddenly in Boston on Jan. 23, of cardiac disease. He was a graduate of the College of Physicians and Surgeons, New York, and fifty-three years of age. Dr. Mott had not been in active practice for some time.

EDWARD BARBILLAC DANA, JR., M.D., of Metuchen, N. J., died from pneumonia on Jan. 23, at the age of forty-three years.

REPORT OF CASES OF TREPHINING FOR EPILEPSY.[1]

BY JOHN C. MUNRO, M.D., BOSTON, MASS.

In reporting the following eleven cases of trephining for epilepsy I wish especially to put on record the clinical histories and the lesions found at operation. By the accumulation of such data from different surgeons some one in the future may be able to make such use of these observations as will determine with greater accuracy which patients are likely to benefit by surgical interference.

I know of no more discouraging field for the surgeon than trephining for epilepsy, and yet I cannot but feel instinctively that there is a small class of unfortunates suffering from this disease which can be helped, probably in a way at present unexplainable. I do not refer, of course, to those with recent palpable depressions of the skull nor to those with new growths, but to those in whom there may be some unsuspected lesion of the cortex, or pia, or dura, a lesion which cannot be diagnosticated except at operation or autopsy. In practically every case reported here there was some pathological lesion or abnormality found at operation but vaguely suspected beforehand. It is far too early to surmise what bearing these findings have on the causation of the epileptic attacks; that element must be left for determination after the accumulation of hundreds of such observations. Whether relief will follow operation in any group or groups of lesions such as have been found here it is impossible to predict.

In the first place, the one important element of the time of operation after the lesion has started to form is of great significance. Until we can collect the cases of late operation to compare with cases of early operation, before the epileptic habit has been formed, we are not in a position to condemn, nor indeed to advocate, early interference. Other things being equal, and judging from analogous conditions elsewhere in the nervous system, any benefit to be derived from mechanical means is more likely to come early in the course of the disease than late.

Unfortunately, the data in the cases reported here are from the naked eye and not from microscopical observation. This is a serious defect, and fully appreciated. To a certain extent it can be corrected in future undertakings.

Owing to the enormous strides in institutional treatment that have been made within the last few years by the splendid enthusiasm of the members of this Association, the surgeon has a still more difficult task ahead of him, to compete with the results now attained by conservatism. It goes without saying that a large, a very large, majority of epileptics are unfitted for operation, no matter how harmless the operation may be, but there is still a small class that stands on the border-line where surgery must be considered, and it is in this class that surgeons must interest themselves and their medical consultants. With the class of patients in whom the epilepsies are due to reflex excitation from lesions elsewhere in the body, — that is, from organized disturbances in the abdomen, pelvis, chest, etc., — this paper does not deal. I feel very sure, judging from the relief to the insane following operations for correction of lesions in the viscera and other organs, that it is important for those in charge of epileptics to search carefully for diseases of the stomach, bile passages, appendix, pelvic organs, etc. When such lesions are present, and of possible significance in producing epileptic attacks, patients should not be denied surgical relief any more than sane or otherwise healthy individuals.

To flatly tabulate my cases on the score of benefit or cure is impossible. In the first place, they have not been under observation long enough, or else they have been lost sight of and the end results cannot be obtained. In the second place, the various lesions come under so many divisions that they cannot properly be compared one with another. Some patients were doubtless temporarily benefited, but whether *post hoc propter hoc* is extremely doubtful.

Several were either not helped, or were worse after operation. Altogether, as was first stated, the outlook is far from encouraging. But if we can see enough cases of living pathology, and eventually can group these cases in numbers sufficiently large, according to the results, the duration of pre-operative attacks, etc., and compare them with the results in similar cases under institutional treatment, we shall be better able to advocate surgical interference or medical treatment, as the case may be.

For the first two cases I am indebted to Dr. F. B. Lund, who has kindly placed them at my disposal. The last three cases are from the Surgical Clinic of the Carney Hospital, one operation being done by my colleague, Dr. J. T. Bottomley, and two by myself.

Dr. F. B. Lund's first case:

C. M., male, twenty-six. Iron moulder. When five years old fell a distance of about eighteen feet, landing on top of his head. Unconscious for three days. At eighteen years of age he began to have attacks of nightmare, crying out. At twenty years of age his right shoulder, caught between two cars, was dislocated. Married at twenty-one, when nightmare became worse, in that, after crying out he would have a general convulsion. Soon he began to throw out his right shoulder during the convulsions.

In March, 1900, Dr. Lund shortened the anterior portion of the capsule of the shoulder, the result being perfect, no dislocation having taken place since. Later he began to throw out the left shoulder, and its capsule was shortened in the same way by Dr. Lund, but relapse occurred after three months during a very severe convulsion. The convulsions always come on in the night, and his wife can sometimes prevent them

[1] Read at the meeting of the National Association for the Study of Epilepsy and the Care and Treatment of Epileptics. Philadelphia, Nov. 5, 1903.

by turning him over in bed. He has bitten his tongue for years and has attacked his wife and children. At times he feels a sensation of dizziness and choking, when, if he gets up in time, he can stop the threatened convulsion. As the convulsions were growing more severe, and he was at times dangerous to his family, it was thought best to attempt operative relief.

Examination in January, 1903, showed a well-developed, very muscular man. On the vertex just to the right of the sagittal suture, at the intersection of a line erected just in front of the ear, perpendicular to Reid's base line, was a stellate scar.

Operation. The scar was turned down in a semicircular flap and a ¾-inch trephine opening made just below it. On opening the dura the pia was found adherent both to the dura and to the brain beneath. On turning back the dura several white spots of dense fibrous tissue were found on the pia, while the brain beneath was lighter and denser than normal, that is, it had the appearance of scar tissue. This scar faded off gradually into normal brain, and its exact limits could not be determined. As the location was close to the motor area it was thought inadvisable to excise the scar. The dura was replaced and sutured. The patient made an excellent convalescence, and eight days later the capsule of the left shoulder was again shortened.

The patient had one or two convulsions while in the hospital and after his return home. In September, 1903, he reported that his attacks were much less frequent and less severe, and that his shoulder had not been dislocated since leaving the hospital.

Dr. Lund's second case:

J. P., male. Fireman, twenty-seven years old. When twenty-two months old was struck in the forehead by the step of a passing engine. The skull was fractured and he was unconscious for a while, but up to five years ago no trouble referable to this injury had arisen and in other ways he had always been well. Five years ago he began to have night attacks, apparently *petit mal*, when he would suddenly stiffen and cry out. Four years ago attacks of momentary unconsciousness during the day began, generally preceded by an aura, described by the patient as a "trembling sensation." When at their worst these attacks came seven or eight times a day, but they have been controlled to some extent by bromides. Has been unable to work much for the past four years.

Examination showed an old ragged scar on the right frontal eminence, just below the hair line. A slight irregularity, but no distinct depression over the bony parts, can be made out.

Operation, Nov. 14, 1902. Dr. Lund. Under ether a semicircular flap was turned down, exposing the injured area, which was roughened but not depressed. A trephine button was removed and the bone found thin at one point. The dura bulged markedly and pulsated forcibly. Beneath the dura, in the right frontal lobe, a cavity the size of an English walnut was found, filled with a translucent semi-gelatinous substance, evidently serum and coagulated fibrin. This was evacuated and the brain beneath could be seen pulsating normally. The membrane lining the cyst cavity was not detached, the cavity being drained with gauze tape.

Nov. 17th. No recurrence of the epileptiform seizures. On the day following the operation the temperature rose to 103° and the pulse became rapid. On removing the wick a large quantity of serous fluid escaped and rubber drainage was substituted for the wick. Since then the dressing has been saturated each day with serum. Pulse and temperature again normal.

Nov. 29th. No recurrence of the seizures. The serous discharge has practically ceased, though there is a small sinus still kept open. Mental condition excellent. Discharged from hospital relieved.

About six weeks after operation the attacks recurred, following closure of the sinus. He was then operated upon by Dr. M. J. Morrisey of Unionville, Conn., who removed a larger area of bone in order to convert the cyst into a cavity which could granulate in from the edges. Relief for a long time followed this procedure, but the attacks have relapsed.

J. S., male, thirty-two. In 1890 patient was wrecked at sea, receiving a compound fracture of the skull. He was picked up by a mail-boat and landed in Philadelphia three days after the wreck, being unconscious all the time. He was then operated upon three times in one of the hospitals, and stated that epileptic convulsions followed these operations. Five years later he was operated upon twice in a Chicago hospital, and at one of these operations, according to his statement, a bit of an instrument as large as the finger-nail was found. Since then he has had but one convulsion, but is troubled with twitching of the hands and arms, and thinks this twitching is more marked on the right side. Does not use alcohol nor tobacco. His family history is excellent. The account given of his various operations varies at times, and it is difficult to unravel all of his statements. After his last operation in Chicago he gained weight, and is said to have had only one severe convulsion, and now complains more of the twitching than anything. At times, during this twitching, he drops anything that he holds in his hand, and occasionally falls. Urine negative.

Shortly before admission, patient stated that he received a blow on the head over the area of trephining, followed by a convulsion on the following day, with vomiting and nose-bleed. No paralysis. In the parietal and occipital regions there are numerous scars showing incisions of the former operations.

Operation by the writer June 11, 1890, at Boston City Hospital. Ether. Left occipito-parietal region covered with scars from earlier operations. Inverted U incision outside the edge of former trephine opening. Posterior and median portion of opening thickened on the edge. The outer portion, where the patient complained of tenderness, was also thickened. The former trephine opening was covered with a thick, tough layer of cicatricial tissue, in which a fragment of gold leaf, said to have been embedded in a previous operation, was seen. The thickened edge was gnawed away until healthy bone was reached, in all, a segment about one inch by a half inch being removed. The pia beneath this portion was dark, thickened and rough. Exploration of the under surface of the bone showed no further abnormalities. Patient in excellent condition after operation.

June 15th. Patient in excellent condition, free from pain, no convulsions or twitching.

June 19th. Wound dressed. Primary union. Has been around the ward for three days. No symptoms except his mental symptoms. He tells many stories of shipwrecks in which he has been—says that he has been an officer on board yachts of the Prince of Wales and of the Rothschilds. Discharged to the neurological department.

Seven months later the patient reported that he had never been so well since the original injury and that he had had only two slight convulsive attacks, each one affecting his right fingers for a moment while writing. He had been in charge of the neurological

department for general nervousness, evidently of a marked character, but it was learned later through an acquaintance that the patient had had at least two or three epileptic attacks of a severe type, he not being conscious of their onset.

L. C., female, fifteen. Italian. Referred to the writer by Dr. H. C. Valentine. Admitted to the City Hospital Aug. 22, 1898.

Father died of Bright's disease. Three sisters and three brothers died in infancy from unknown cause.

When fourteen months old she fell, striking her head. Convulsions followed for a while and then disappeared for several years. She has frequently bitten her tongue, and from her friends she knows that her face twitches considerably during an attack. The attacks come irregularly, sometimes once a week, or every day for a week, and then at intervals of a month or more.

Examination of the head, negative.

Referred in consultation to Dr. W. N. Bullard, who advised exploratory trephining.

Operation. Ether. U-shaped flap opening over arm center, on right side. Protusion and very faint pulsation. Dura not thickened. Skull thick and tough, but apparently not pathological. Opening enlarged considerably and the dura slit. No excess of subdural fluid. Ventricle tapped, but no excess of fluid found. At one spot on a convolution, apparently at or near the arm center, the cortex looked darker and more opaque than normal over an area about three-eighths of an inch in diameter. This area was excised for diagnosis. Elsewhere the brain looked and felt normal. Pulsation had returned after the various tappings, but without any evidence of an excess of fluid having been withdrawn. Dura sutured loosely and the skin closed, allowing for a rubber tissue drain.

Aug. 26th. She rested poorly during the night after operation, and had several spasms early this morning, complaining of headache.

Aug. 27th. Much better, slept well, no symptoms.

Aug. 29th. Wound dressed. Clean. Wick removed.

Sept. 2d. Wound practically healed, one spasm early this morning.

Sept. 15th. Patient has been up and about the ward for a week, always in company with another patient. No subjective symptoms. Discharged to neurological department.

She improved for several months, then returned to Italy and has been lost sight of.

The specimen returned for examination was lost.

J. E. E., male, aged twenty-six, carpenter.

Was seen with Dr. L. F. Hatch in December, 1897. Family history excellent, general health good. Knows of no causative injury to his head, except a blow while coasting when a boy of twelve. Was not unconscious at that time and did not regard the injury as of any moment.

When about twenty years of age his first and most severe epileptic attack came on, without any warning. The attack lasted throughout the night, one convulsion succeeding another. Two days later the convulsions returned, lasting for three weeks, the separate fits following one another at intervals of a few minutes to an hour. Since then they have come on more or less frequently at intervals varying from a week to three months. One year ago had a severe attack, and was more or less upset for a week with exhaustion and mental disturbance. Lately the attacks have been less severe, but he has complained more of dizziness than heretofore. The attacks come by night or day, with warning, lasting for about five minutes. The attacks themselves last about two minutes. He does not lose consciousness, though he may do things of which he has no recollection. Rarely bites his tongue. The attack starts with spasmodic flexion of the left leg and thigh, spasm of the left trunk muscles and spasmodic abduction of the left upper extremity, which can be controlled, in the lighter attacks, with his right hand. The head is drawn to the left. There is no frothing at the mouth.

He has been on mild bromide treatment, as heavy doses affect him mentally, and he refuses to take the drug except to temporarily control his dizziness.

General physical examination, negative.

Was seen in consultation by Dr. W. N. Bullard, who advised trephining.

First operation at Boston City Hospital July, 1898. Ether. Trephine opening made over the fissure of Rolando near or over the leg center. Dura pulsated very slightly and was more tense than normal. Upon being opened, serum escaped in moderate quantity. Electric current used to stimulate the centers, but the result was unsatisfactory. In the sulcus, apparently at its superior genu, there was a depression filled with edematous pia, the latter having opaque white spots about an eighth of an inch in diameter, in its substance. These spots extended anteriorly and laterally for a short distance beyond the limit of the bone opening. On both sides of the depression, in the sulcus, the convolutions felt normal. Exploration with a director failed to show anything abnormal within the brain. Towards the end of the operation, though the brain bulged slightly, there was much better pulsation. The dura was stitched lightly and the skin sutured, leaving an opening for a temporary drain of rubber tissue.

Convalescence was satisfactory, and he was discharged in two weeks for observation and medical treatment. There was no definite gain for about six months, when he began to improve, but in the spring of 1899 he had a series of severe convulsions lasting two weeks. After this he had no attack until November, 1899, after which date he had two slight convulsions, and he considered himself a good deal improved. He found that he could work most of the time, the attacks being limited to slight dizziness without loss of consciousness. He feared, however, a severe outbreak in the coming spring and was anxious for another operation.

After further consultation with Dr. Bullard, a second operation was performed in May, 1900, again at the Boston City Hospital.

Second operation. Ether. Horseshoe incision, carried about three-quarters of an inch beyond the old scar. In dissecting the dura from the brain in the old opening, the brain was intimately adherent in the posterior half. Anteriorly it was not adherent, pia being cloudy, bluish and with opaque spots, as at first operation. From the edges of the bone there were growing several flat projections, not pressing inwards against the brain, but apparently being new bone shooting out from the edge of the first trephine hole over a distance of an eighth to a sixteenth of an inch. The opening was enlarged forwards for an inch and the dura reflected, showing a cloudy, bluish pia with opaque spots, more or less enclosed in a triangle of large veins an eighth of an inch or more in diameter. These veins were ligated with catgut at the periphery, and the enclosed pia, with its small piece of convolution, was removed. Beyond this area the pia appeared to be healthy for the most part. Several pial and dural vessels gave troublesome hemorrhage. The dural flap was sutured and the skin closed, allowing for an iodoform gauze wick drain.

The patient stood the operation, which was a long

one, fairly well. Within twelve hours he had a general clonic convulsion and a left hemiplegia was noticed by the attendant for the first time. Face and tongue not involved. The paralysis of the lower extremity disappeared by the fifth day, and by the time of his discharge, sixteen days after operation, the paralysis of the upper extremity was disappearing, although all motions were weak. After two months of electrical treatment all paralysis disappeared.

Five months after operation there had been no definite improvement. He had had occasional convulsions, the attacks starting in the left upper extremity and not in the leg, as heretofore. He has bitten his tongue occasionally. The dizzy spells which had troubled him before operation, however, had disappeared.

I then lost sight of him until October, 1903, when he reported that up to November, 1902, he had had attacks every few weeks but without interference with his work. Since November he had gone ten months without any attack, but in the last month he had had two or three very slight attacks.

In his old attacks he always had a forewarning, often feeling a strong desire to run away to some place and lie down, but latterly the attacks come on easily, without any feeling of fear or weakness, and he keeps at work and goes about without fear of a general convulsion. Has had only one night attack since operation.

His left hand is as strong as before, but the fingers are a little clumsy in handling small nails, that is, he is slow to pick up and adjust a nail. He feels that his fingers are not so responsive to his will as before operation.

His general health is good, and mentally he seems to be the same as when he first consulted me. He takes from 1 to 3 dr. of bromide after his work is over, and has done so for months, but the amount is less than that which he was taking when the attacks were severe.

He himself feels that there has been a marked and satisfactory gain, but, like myself, he is skeptical as to the *role* played by the operation in the improvement.

Examination of the firm depression at site of operation shows no tenderness.

T. M., male, nineteen. Student. Referred to the writer for operation by Dr. P. C. Knapp, who has kindly given me the following history, which I quote in his own words:

"T. M. Consulted me first April 24, 1899. Family history: Father excessively hysterical, mother extremely nervous, mother's brother had hemiplegia with ephasia. This young man had always been in good health until the autumn of 1897, when he was shut up in a closet at school by some of his schoolfellows and endeavored to get out over the transom. The transom fell upon his neck, and he was said to have been nearly strangled. Not long after, while playing football, he was kicked in the back of the head, but was not rendered unconscious. Some time in the following spring he began to have attacks in which he suddenly lost consciousness, moaned slightly and fell forward without any convulsive movement. When I first saw him he was having a number of these attacks each day, and they would come on in his sleep, throwing him out of bed. He had several of these attacks under my observation, in which he suddenly fell forward from the chair to the floor and gave a slight moan. There was a slight quiver of the limbs. After forty or fifty seconds he regained consciousness, seemed somewhat dazed for two or three minutes, and then picked himself up without further trouble. One of these attacks came on while examining his head and pressing upon the place where he said he had been kicked.

"Physical examination was negative, except that the right arm was somewhat weaker than the left and there was a very slight blunting of sensibility there. He was a very powerful, muscular fellow, of good habits, and with no history of previous disease. Examination of eyes negative.

"He continued during the term as a student, doing well in his studies and being apparently normal in the intervals between his attacks. Under bromide the attacks diminished very markedly in number, so that by June he was having them at the rate of one in two or three weeks. He was given a mixture of bromide, codeia and adonis vernalis. In July he went with his family to the seashore, and while there continued the above treatment, having attacks at longer intervals, once in three or four weeks. He seemed to his family rather nervous in regard to these attacks and to be considerably disturbed because he had one or two of them in company. In August, while at the seashore, he states that he saw some rum in the house and took a large drink, nearly a cupful. His brother regards this statement as exaggerated — he probably took very little. Soon after that, in the evening, he was attacked in a different form from his previous attacks, having the idea that he saw snakes, which were coming toward him, and became violently maniacal for a period of from half an hour to an hour, struggling violently with every one who came near him. The attack ceased instantly as soon as the physician who was called inserted the needle under the skin to inject morphine. The following day he had one or two more attacks and was taken to Winchendon. While there he had several similar attacks, in which he was extremely violent — split open the straightjacket by muscular contractions, simply throwing his shoulders forward, and was more than four strong attendants could handle. In the intervals between the attacks he was perfectly rational, bright, cheerful and normal. At the request of the family he was brought to the Boston City Hospital for operation."

Aug. 9, 1899. Operation. Dr. P. C. Knapp and Dr. Taylor of Sag Harbor present. Ether. U incision in the right occiput over tender area. Trephine button adherent to dura. Nothing about the skull in the neighborhood felt abnormal. Dura quite firmly adherent along the right lambdoidal suture. The dura bulged into the opening and scarcely pulsated, its tension being abnormally increased. It was then opened, and the brain bulged out to beyond the outer surface of the skull and scarcely pulsated. The opening enlarged to an inch and a half in diameter. Nothing definite was felt on palpating the brain except the abnormal tension. A director carried around outside and inside the dura showed nothing. Without more definite localization, and on the chance that more extensive exploration would be needed later, it seemed best to stop and complete the operation at another sitting. Dura not closed, skin sutured, allowing for rubber tissue drain. No shock followed operation.

Sept. 20. Patient has been up and about the ward and out of doors for some time past. No convulsion for seven or eight days. Discharged relieved.

A better result followed the operation than was anticipated. Considerable fluid oozed from the wound for a while. The protrusion of the brain disappeared, leaving a normal pulsating scalp, and the convulsions became much less severe and frequent, and by the end of six weeks he was so much improved that it was deemed best to discharge him in the care of a physician and await developments.

To return to Dr. Knapp's report:

"During the convalescence from the operation he had a few attacks in which he saw snakes and became violent. He had only one in my presence, and that was very brief. I learned afterwards that he stood in considerable awe of me. Other attacks were suppressed by throwing cold water upon him. He was taken to Bloomingdale, where he remained for a number of months. While there he had comparatively few attacks, and after a time he felt himself that his condition had cleared up and that the operation had been an excellent thing for him. While at Bloomingdale he made an attempt at suicide, which was apparently merely a dramatic display, without any real intention to commit suicide.

"In May, 1900, he returned to Boston, expressing himself as feeling well, but weak. The following autumn he resumed his studies, and had no more attacks of either the convulsions or maniacal outbursts, but he frequently spoke of having attacks of weakness in which his heart gave out. During the following year he complained a good deal of his heart, as having attacks of palpitation and cardiac weakness, but there was never any objective evidence of any disturbance of the heart. At one time he went to his physician in Cambridge, dropped upon the lounge and stated that he had taken an overdose of digitalis and was suffering greatly in consequence. On investigation, the amount of digitalis taken was small, and he showed no indications of digitalis poisoning.

"He was for the next year or two, while under observation, decidedly hypochondriacal, had more or less digestive disturbance; but was free from any convulsive attacks. He continued to do his work as a student, graduated with high honors, and finally married, since which time I have heard nothing of him."

G. A. L., male, twenty-one years old. Referred to the writer by Dr. H. O. Benner. One of sixteen children. Always well until June, 1896, when he was hit high up on the right side of the head with a bottle. A month later he fell from a swing and was unconscious for four or five days. In falling he is said to have struck the left side of his face. Hemiplegia followed, disappearing in two or three months, after treatment at the Framingham Hospital. Following his discharge in September, a clear history cannot be obtained, but no account of convulsions can be secured from the family, while he was at home, until February, 1898, since which date they have been growing more and more severe and his mental condition has been steadily deteriorating. The convulsions come at intervals varying from five days to three months, and lately he has been very irritable and cross. There is no family history of epilepsy on either side, but the family is unintelligent. No definite history of alcoholism in his parents can be obtained.

Operation Sept. 26, 1900, at the Framingham Hospital. Ether. Just before operation he had six convulsions, the spasms, according to the observation of the nurses, beginning in the right foot and remaining most marked in the right lower extremity. Horseshoe flap over the upper end of fissure of Rolando, on right side, where lay a well-marked scar. The bone itself showed no evidence of injury; the dura, without thickening or opacity, was moderately tense and pulsated slightly. The opening was then enlarged medianwards nearly to the edge of the sinus and downwards along the line of the fissure. On turning back the dura, the fissure of Rolando, an anterior and a connecting fissure, showed opaque white pia stretched across, with enlarged veins beneath. The pia was cut in line with the fissures and some of it removed. The enlarged vessels were ligated with catgut. Palpation showed no evidence of tumor. There was moderate bulging of the brain, which could be pressed back without difficulty. The dura was sutured lightly and the wound closed, allowing for a rubber tissue drain.

After operation the mental condition improved quite a little. The wound healed aseptically, and he had no convulsions until Oct. 12, when he had seven.

Oct. 26th he had four slight convulsions; Nov. 13th, six bad convulsions; Nov. 22d, one slight convulsion, while in the street.

For two or three months he seemed to improve somewhat, the attacks not coming so often nor being so severe in character. After this, however, he became worse, and about two years after operation he was committed to an insane asylum.

E. O'B., female, seven years of age. Admitted to the Boston City Hospital Jan. 16, 1900.

Family history negative. Talked well at eighteen months and was a bright child until the accident.

Four years ago fell from a hammock, getting up and running about as usual. A lump the size of an egg appeared in the occipital region shortly afterwards. She was well for a week, when, early one morning she had a universal spasm, — the tongue not being bitten, — and she became unconscious. She was kept under ether all day, the spasms returning as soon as the ether was removed. For three weeks after this she could not talk plainly, and the left side was paralyzed. A month later she is said to have been well, then had a slight convulsion and fell, but without loss of consciousness. The convulsions since then have come on three or four times in the day, with occasional intervals lasting several months. Dec. 26, 1899, she fell down a flight of stairs. No convulsion at the time, no loss of consciousness. But since then has had five slight convulsions. Does not bite the tongue and knows when the attacks are coming on. The convulsions are first tonic, becoming clonic. Appetite at times ravenous, at other times poor. The child is feeble-minded, feeds herself with a spoon, and does not talk as plainly as formerly. Unable to go to school on account of restlessness; at times is cross and violent. Seen in consultation with Dr. W. N. Bullard.

Examination shows her to be a mouth-breather, with protruding tongue, drooling constantly, and with a vacant stare. Skull shows a symmetry in the right occipital region, with a rounded protrusion 3 cm. in diameter. Pupils react normally. Is right-handed.

Jan. 16. Slight convulsion to-day; did not bite tongue nor lose consciousness.

Jan. 19th. Operation by writer. Ether. U-shaped flap. Button removed a little in front of the motor center and low down. Enlarged upwards, forwards and backwards. No pulsation of dura, no enlargement of the meningeal vessels that lay across the opening. Dura about twice the ordinary thickness and slightly adherent to the bone in front of the coronary suture. The dura was opened anterior to the meningeal vessels, and a cloudy edematous pia bulged out beyond the level of the dura. On puncturing the pia considerable pial fluid escaped; no subpial fluid. With the escape of the fluid pulsation appeared. A director passed into the brain met with moderate resistance about half an inch from the surface. With the loss of fluid and retreat of the brain from the skull, the finger passed over the surface, felt that below the trephine opening — that is, nearer the temporo-sphenoidal area — the brain was more indurated than

elsewhere, but no definite growth could be determined. With the escape of the fluid the pulse rose considerably, but not alarmingly. The brain itself looked normal, the pia being cloudy and the dura thickened. Dura lightly sutured and the skin sutured, allowing for capillary drainage.

Jan. 21st. Wick removed. Slight serous discharge. Wound clean. No symptoms.

Jan. 30th. General convulsion to-day; first one since operation.

Feb. 7th. General convulsion. Pupils were dilated and did not react to light. No deviation to the eyes. Mouth open. Did not bite the tongue. Apparently unconscious. Incontinence of urine during the convulsion. Left hand open; the right fingers clinched over flexed thumb. Convulsions more marked on right side, the whole attack lasting about ten minutes. Afterwards she was drowsy and slept for a while.

Feb. 7th. Second operation. Ether. U-shaped flap in occipito-parietal region, the anterior leg crossing the scar of the posterior leg of the first wound. Under the first wound the space between the dura and the skin was filled with tough granulation tissue, the dura itself not being thickened nor appearing abnormal in any way. Starting from the posterior edge of the old trephine opening, a large space was gnawed out posterior to the lambdoidal suture and inferiorly nearly to the level of the tentorium. Throughout the whole of this area, after opening the dura, which pulsated slightly, the pia was cloudly, as at the first operation, and bulging from serum which leaked out steadily. The pia in the posterior — that is, occipital portion — was seen to stretch over a large cyst cavity, with several tortuous vessels of the size of a normal superior profunda artery running in its meshes, intermingled with a bunch of congested veins and a lot of yellowish strands that resembled scar tissue. On opening the pial membrane between the vessels a spherical cyst, two inches in diameter by measure, was found occupying the region of the occipital lobes or else pushing the latter forward, producing in this way the indurated condition found at the first operation. The posterior wall of this cyst was formed by the skull, the inner wall was formed, apparently, by the central ganglia, and the wall of the lateral ventricle, as a bluish translucent area, could be seen in the region of the ventricle. The floor was formed by the tentorium and the anterior wall by compressed brain, the latter projecting backwards slightly at the surface, forming a distinct, sharp edge. The cyst contained yellowish serum. The dura was sutured with catgut, leaving an opening posteriorly for drainage. The scalp was sutured, allowing for a cigarette drain.

The patient stood the operation fairly well, the pulse rising with the evacuation of serum.

Feb. 9th. Drain removed. About 3 dr. of clear fluid escaped. Wound clean.

Feb. 12th. Very irritable. Temperature 101.

Feb. 17th. Wound healed except at the lower angle, where rubber dam allows serous discharge. Sinus two inches deep, half an inch in diameter. Rubber dam drainage.

Feb. 25th. General convulsion. The first one since the second operation.

March 1st. General convulsion.

March 4th. Sinus healed. Drainage removed. No discharge.

March 20th. Wound healed. Apparently no mental improvement.

March 21st. Patient apparently improved for a while after second operation, and then elapsed back into original condition.

March 21st. Third operation. Ether. Short incision. Half an inch in front of the posterior edge of the skull an opening was made. Beneath this opening lay the expanded brain tissue, somewhat edematous, with a clear pia. Posterior to this was a small cystlike depression not over half an inch in diameter, from which clear serum escaped. So far as could be told, the brain had expanded to within one half an inch of its normal limit. Rubber tissue drain. Wound sutured. Gauze dressing.

March 25th. No improvement. Good appetite. General condition excellent.

March 31st. There has been, possibly, slight improvement in general condition, more marked some days than others. Is more careful about wetting the bed and drools less. Mentally she seems to be a little improved, but still has epileptic attacks. Over the area of trephine opening there is normal pulsation.

Discharged relieved.

The three following cases are from the Surgical Clinic of the Carney Hospital:

CASE XXXI. S. V., male, thirty-three years old. Harness maker. Referred to writer by Dr. H. C. Valentine.

Family history negative. When eight years of age a wagon-wheel ran over his head, leaving a scar on the right side near the inner orbital angle. In October, 1899, he was struck on the head by a block of wood, the skull being exposed. He was unconscious for a time. One year later he began to have a tingling sensation in the ends of his fingers in the right hand, but not in the thumb. In October, 1902, these tingling sensations, instead of passing away, were followed by flexion of the fingers and of the wrist, with tremor of the arm, followed by stiffness. He describes a feeling as of "something tightening" inside his head before he becomes unconscious. Since October he has had three attacks, in February, May and June of this year. The attacks come about 4 A.M. and last half an hour. Otherwise he is perfectly well. Seen by Dr. W. N. Bullard, in consultation, who advised operation.

June 13th, 1903. Operation by writer at Carney Hospital. Ether. Trephine opening made over the arm center on the left side. Dura tense, bulging, with very slight pulsation. Pia and brain beneath the opening normal. Forwards and upwards, beneath the scar in the scalp, was a slight, smooth, rounded bulging on the inner table. This was removed with the rougeur. On opening the dura at this place the pia seemed normal. The cortex in this convolution of the anterior arm center looked a little more opaque than the posterior convolution; otherwise negative. The ventricle was tapped and several drachms of clear fluid escaped under moderate pressure. Pulsation and tension returned to normal. Dura loosely sutured and skin closed, allowing for a rubber tissue drain. The patient had a little headache following the operation, but otherwise convalescence was satisfactory. On June 25th he was discharged with the wound healed, normal pulsation of scar, and with no subjective symptoms, except slight pain in the right forearm in the afternoon and occasional tingling in the tips of the fingers of the right hand.

Oct. 31st. Patient reports that he has had no epileptic seizures and has gained twenty pounds. About once a week he has a fleeting tingling in the right fingers or anterior surface of the wrist, but without any twitching, and the headaches have disappeared. He has returned to his regular work. There is normal pulsation of the scar and he appears to be in good general health.

No. 223. M. L., school boy, fourteen and a half years of age. Father died with meningitis and several members of the family have died of pulmonary tuberculosis. Patient always strong and healthy. In August, 1903, while stooping down to examine a leak in a hose pipe, he remained stooping for some time, until discovered by his brother, when he seemed dazed, and at first did not answer when spoken to. He remained in this condition for four hours, when he recovered consciousness, spoke and recognized his friends, but complained of steady severe headache on the right side of his head, and vomited. During the night he slept well, but awoke with headache, from which he recovered almost completely. Twelve days later he was sent to a store on an errand, and as he did not return his mother went in search of him, and found him in another store in a dazed condition similar to that in his preceding attack. Two days afterwards the left side of his face began to twitch, he frothed at the mouth, bit his tongue and became unconscious. Chloroform was given to relieve the attack. He entered the hospital Sept. 1st, still suffering from similar attacks, except that the left arm was involved in addition. He had two attacks on the cars going to the hospital.

Physical examination. Negative. Patient complains of headache.

Sept. 2d. Four spasms to-day. Conscious but unable to speak. Knows when the attack is coming on and gets into bed. Has severe headaches afterwards. Is promptly relieved by choloroform.

Sept. 3d. No frothing at the mouth in the attacks to-day. Left arm and leg involved.

From Sept. 4th to the 8th he had two or three convulsions a day and at times seemed very stupid. No Babinski; knee jerks normal; eyes normal.

Sept. 10th. Delirious at times and stupid between the attacks of delirium. Is apparently worse.

Sept. 11th. Operation by Dr. J. T. Bottomley at Carney Hospital. Ether. Trephine opening over the face center of the right side. On opening the dura the brain protruded, but nothing particularly abnormal was found, except that possibly the brain appeared somewhat softer than usual. Several attempts to tap the ventricle brought no fluid. The opening was enlarged backwards and upwards and a small portion of the brain tissue approximately over the face center excised. Dura sutured and skin closed. He recovered well from ether and complained only of slight headache. No paralysis nor convulsions followed the operation, and twelve days later, when he was discharged, he had had no return of his symptoms, the pulsation over the wound being normal.

When heard from Nov. 1st there had been no return of his trouble.

F. L. K. No. 352. Carriage painter, referred to the writer by Dr. Hamblen of Bedford and Dr. W. N. Bullard. Thirty-nine years old, without history of insanity, alcohol or tuberculosis in his family.

Struck the right fronto-parietal region of his head, three to four years ago, against a protruding knob in the limb of a tree. The blow was not a severe one, but was followed by a lump which persisted for several months. From the time of the accident he has had more or less pain at the seat of injury and immediately preceding his epileptic seizures the pain is increased.

The first epileptic attack came in June, 1903, and headaches which he had been complaining of before that time became severe, at times "almost driving him crazy." These headaches lasted from a few minutes to twelve hours. His first attack came while he was working in a garden on a hot day. He was unconscious for one and one-half hours.

A week later he had a second attack, falling off of a couch. Under bromides he went without an attack for five weeks, when, after overeating some bananas, the fits returned, coming at first every week and lately every day or two.

He is said to have had pulmonary tuberculosis some years ago, with subsequent healing of the cavities. He also had excision of the left elbow for tuberculosis, at the Waltham Hospital, six years ago, with excellent result. Otherwise he is a healthy, strong man.

His attacks begin with choking or gurgling, clinching of both hands, spasms of legs, relaxation and cyanosis. In some attacks he has bitten his tongue badly.

In right frontal bone, just over coronal suture and two inches from median line, is a slight depression of skull which is always and distinctly tender to pressure.

Operation by writer, Oct. 31st, 1903, at Carney Hospital. Ether. U-flap within the hair line. Trephine opening a little posterior and to outside the depression, which lay in the coronal suture. No depression of inner table. Normal tension and pulsation of dura. Opening enlarged forwards to include sensitive area. On turning back the dura the pia-arachnoid in this region appeared markedly opaque, edematous and at least $\frac{1}{16}$-inch thick. In the meshes were numerous grayish, opaque miliary nodules, tubercular in appearance. The largest of these were dissected off with the including membrane. Subdural exploration in the neighborhood failed to show any bony depressions. So far as could be told the lesion was confined to the region of operation. Pressure on the pia-arachnoid forced out the edema. The brain itself looked normal. Dura sutured loosely and the skin closed allowing for a rubber tissue drain. No shock.

SOME CONCLUSIONS BASED ON A STUDY OF ONE HUNDRED AND THIRTY-FOUR CASES OF CALCULUS IN THE URETER. WITH A REPORT OF THREE NEW CASES.

BY BENJAMIN TENNEY, M.D., BOSTON.

Case I. Reported through the courtesy of Dr. J. W. Elliott. Female, thirty years of age, previously operated on for gallstones and later for adhesions about the pylorus.

Sixteen days before entering the Massachusetts General Hospital she had a severe attack of pain in the region of the right kidney, extending down the right leg, not entirely relieved by a grain of morphine. The next day she passed bright red blood in her urine. Subacute pain was present all the time, and she was under the influence of morphine most of the time.

On examination some resistence and tenderness was found in the right flank. Urine was brownish-red in color and showed a slight trace of albumen, and the sediment contained considerable pus and red blood corpuscles.

The x-ray plate showed a shadow in what would be apparently the course of the right ureter, one and a half inches above the crest of ilium.

Operation, Feb. 5th, 1901. Patient on left side. Long incision across loin, dissection carried down to kidney. The kidney and ureter were exposed, and the ureter was found dilated about two inches below the pelvis. A calculus was felt at the lower end of the dilatation. Ureter cut and calculus removed. Ureter sutured with interrupted silk intestinal sutures. Wick of gauze left in for drainage.

Feb. 12, patient complained of blindness and had four convulsions. Passed 15 oz. of urine on the day previous with 6 grm. of urea. No vomiting — able to swallow. The patient became comatose and died during the day.

At autopsy — a hemorrhage was found under the capsule into a small cyst in the right kidney. Cavity in kidney showed no definite lining. Capsule adherent. Cortex 5 mm. thick, and pale. Renal calices and pelvis slightly dilated. Complete healing apparently taken place at point of incision in the ureter. No stones found anywhere. Left kidney showed a number of small cysts filled with a gelatinous straw-colored material. Renal substance presented no other lesion worthy of note.

CASE II. For the privilege of reporting this case, I am indebted to Dr. J. F. Thompson of Portland, Me.

Female, aged twenty-seven. Came to the Maine General Hospital in June, 1901. She gave a history of pain in the left side, paroxysmal in character, which began in the region of left kidney and extended down along the line of ureter into her pelvis. Pain had been present several months. Urine showed red blood corpuscles and an occasional white cell. There was also tenderness on pressure. Provisional diagnosis, stone in kidney.

At operation the kidney and pelvis were thoroughly explored and no stone found. The ureter was not examined. Capsule was slit and the kidney replaced without drainage. Pain was entirely relieved for several months, but returned.

She came to the hospital again in May, 1902, with severe pain in the region of the left ovary and very little pain in back. Hysterectomy was advised and performed by another surgeon, but no relief followed the hysterectomy.

Her attacks of pain continued till February, 1903, when the pain suddenly ceased, and within a few days she passed a calculus the shape of a beechnut, about one-quarter inch in longest diameter. Since then she has had no pain.

CASE III. Personal.

Female, thirty-six. Nurse. In 1893 a double ovariotomy was performed in Washington, D. C., after seven years of invalidism. The details of this I have not been able to get from the surgeon. Her recovery from the operation was slow, but she steadily improved until December, 1901.

In 1899 she had an attack of colic in the right side, which was supposed to be due to "congestion of the liver." December, 1901, she had an attack of renal colic in the left side, lasting from 8 A.M. till the next day, during a part of which she was delirious.

She had an attack in March, 1902, and again in August and November. Previous to the attacks of colic she noticed that she passed less urine than usual, and after the attacks there was always an increased quantity for twenty-four hours.

During the attacks the pain extended downwards into the bladder, but was never referred to any other location than the urinary tract. Nausea always followed the attacks. She usually had a time of "not feeling just right" for an hour or so before the colic began.

Following the attack of December, 1901, she had some hematuria. At time of examination, January, 1903, her urine was 1002, clear, and showed almost no sediment with the centrifuge, but there were a few epithelial cells and some red and white blood corpuscles. There was decided tenderness along the line of the left ureter, from the left of the umbilicus down. Vaginal and rectal examinations showed nothing abnormal except marked tenderness at entrance of left ureter into the bladder. An attempt was made to catheterize the ureters without anesthesia, but the posterior wall of the bladder was held back so that the orifices of the ureters could not be made out, even with knee-chest position. An x-ray examination was suggested, but refused by the patient. Provisional diagnosis — intermittent obstruction of the ureter probably due to stone. Operation Jan. 14, 1903. Dr. H. M. Chase assisting.

Incision posterior to border of external oblique. Kidney exposed — normal color and about double normal size. Walls of pelvis and of ureter decidedly thickened. No stone or other obstruction found within reach of hand.

The skin incision was continued downwards along the line of ureter and a second opening through the muscles made by separating their fibers over the point where the ureter crosses the iliac artery. The ureter was lifted up with the peritoneum, but quickly isolated by means of intermittent traction on the kidney through the upper opening.

Following the ureter from the upper to the lower incision the fingers met without discovering anything abnormal. Following the ureter into the pelvis, a nodule was felt an inch below the point of crossing the iliac artery.

After considerable manipulation the nodule was pushed up and followed along the ureter into the pelvis of the kidney, from which it was removed through a small incision. It was intended to pass a catheter through the pyelotomy wound into the bladder, but the ureteral catheters had been boiled, and it did not seem advisable to pass such ragged instruments, so the ureter was followed down with the fingers to its insertion in the bladder wall and no further obstruction was found. The pyelotomy wound was closed with a catgut suture. The lower abdominal incision was closed up solidly, and a wick of gauze was left in through the upper incision for drainage. The stone measures 1 cm. long, 8 mm. wide and 5 mm. thick. It is very rough and shows a groove on one flattened surface.

Seven hours after operation she was catheterized and four and a half ounces of smoky urine, with a large trace of albumen, was withdrawn.

Her convalescence was uneventful, except that on the 21st day she had a sharp attack of colic which lasted for about two hours and following this there was again a passage of smoky urine. No crystal was seen at this or any subsequent time. Her urine has been examined at least once a month up to July, 1903, and has shown neither blood or albumen since Feb. 22d.

In spite of the rarity of these conditions there is already a considerable literature on the subject. An article by Dr. Benjamin R. Schenck, in Vol. X of the Johns Hopkins Hospital Reports, closes with a very accurate table of 101 cases, nearly all of which have been verified from the original reports. To this list I have been able to add thirty-three cases, which appear in a table at the end of this article.

One very striking thing in connection with the detailed history of these cases is that a large proportion of patients had been previously operated upon for some other condition. In at least four cases gallstones were removed, in two cases operation was performed for extra-uterine pregnancy, in one case a variocele was operated on, in several cases appendices were removed, but the most frequent previous operation was ovariotomy. Probably very few of these were operations for mistaken diagnosis, as abnormalities undoubtedly existed in the organs previously approached, and yet this suggests the difficulty of diag-

nosis between the symptoms produced by an impacted ureteral calculus and certain other pelvic and abdominal conditions.

Seventy-four of these cases were females and fifty-eight males, the sex not being stated in two cases.

SYMPTOMS.

The suffering and shock from an attack of colic may be sufficient to produce vomiting, fainting, delirium, temporary paralysis of the intestines, and be followed by very great physical prostration, or it may be described as a discomfort or heavy sensation in the side. The pain is felt in the loin, in the pelvis, in the urethra, in the testicles, and, in one case, was referred to the inner side of the thigh.

Between the attacks there is usually a period of freedom from pain, which may last for a few hours or for months. The pain seems to come on when the urine is dammed up behind the stone, or when the calculus is moving from one location to another. Preceding the attack there is sometimes a period of discomfort, with a diminished excretion of urine, which the patient learns to recognize as a warning. Following the attack a polyuria amounting to some pints within a few hours may appear. These symptoms of an intermittent hydronephrosis are reported in many of the cases. There is nothing about the pain which in a single attack will surely differentiate it from some other abdominal conditions, but the history of repeated attacks of the same or similar character makes the pain and its location valuable aids to diagnosis.

Another symptom is the presence of blood in the urine. Tuffier [1] considers that red blood corpuscles in the urine after physical exertion, and a history of recurrent attacks of colic, make sufficient evidence on which to base a diagnosis of stone above the bladder. This condition of recurring pain with slight hematuria may persist for years without causing further symptoms. In one case the attacks of pain extended over a period of thirty years, but it is unlikely that a stone of sufficient size to produce real obstruction can remain so long without causing damage to the urinary tract above its location.

Most of the writers on this subject agree that the symptoms of stone in the ureter are not often to be distinguished from those of stone in the kidney. This seems to be especially true where the stone is located above the brim of the pelvis. With the stone located below this point, the pain is more apt to be referred to the bladder — sometimes to the testicle in the male and sometimes to the urethra in either sex.

LOCATION.

The location of these stones in the ureter has been in a general way in one of three places which correspond to the points of narrowing described by recent writers on the anatomy of the ureter.

The first point of narrowing is about 7 cm. down, the second just above or below the brim of the pelvis and the third as the ureter enters the bladder wall.

Henry Morris [2] and Byron Robinson [3] practically agree in giving the diameters of these three points of narrowing; the first being about 3.2 mm., the second 4 mm. and the third about 2½ mm.

The number of stones in this series of 134 cases caught in the different locations corresponds very nicely to these diameters — 35 being caught in the first isthmus, 18 in the second and 73 in the third. In the other cases the location is not definitely given.

DIAGNOSIS.

Guyon,[4] in a recent article, insists on the great importance of the recurring pain located on one side of the genito-urinary apparatus, coming on with a sort of aura for some hours before the real pain begins, and the hematuria, which is greater after exercise and less after rest. He is certain that neither the kidney nor the ureter is sensitive to the presence of smooth concretions which do not obstruct the flow of urine, and that some such concretions do reach the bladder without causing pain enough to be noticed.

Abdominal palpation seldom gives information beyond localizing the tenderenss on one side along the course of the ureter. In one case only has the stone been felt through the abdominal wall, and this in a very thin subject.

The presence of a tense or fluctuating tumor from hydro- or pyelo-nephrosis or hydro-ureter indicates an obstruction of some sort below such tumor which may or may not be stone.

Morris states that a calculus within two and a half inches of the bladder may be felt through the vagina, and through the rectum if within one and a half inches. Sometimes if a stone cannot be felt through the vagina or rectum, the presence of tenderness in the lower part of the ureter is of value, as indicating some trouble in the ureter higher up.

A stone may be felt in any part of the ureter after opening the abdominal cavity, and the diagnosis has been made in this way in fourteen cases.

The cystoscope gives information of value where the stone is impacted in the bladder wall or projecting into the bladder. When it is higher up, the ureteral orifice may be seen to be reddened and itself projecting into the bladder. In two cases the absence of the urinary jet from one ureter has led to the diagnosis of complete calculous obstruction.

The waxed bougie described and used by Kelley [5] of Baltimore may be of value, but has been little used in these cases. Guyon thinks the results of its use are dependent on too many conditions, and considers the sensation conveyed

to the fingers through a gum elastic catheter to be more trustworthy.

Without doubt the x-ray is a most valuable aid to diagnosis. It gave a shadow in fifteen of these cases, and no shadow in one. Noble [6] reports a case in which two negatives, taken by an expert at an interval of some days, showed a distinct shadow in the pelvis and in which no stone was felt at operation.

Kreissl [7] reports a case with the symptoms of calculus in the ureter and a shadow on the x-ray negative, in which the ureteral catheter from the bladder and a bougie passed downwards from the kidney, failed to discover any obstruction.

Examination of the urines from the two kidneys separately should give useful information in many cases, but the mechanical damage produced by the instrument or some other lesion in the supposedly healthy kidney may confuse the observer.

With all these aids to diagnosis, the fact remains that recurring attacks of colic referred always to the same side and with pain radiating downwards along the genito-urinary tract accompanied by hematuria, with usually a diminished quantity of urine before and during the attack and an increased quantity after the attack, are the most reliable indications of a stone impacted somewhere between the kidney and the bladder.

The exact location of a stone can often be determined by some of the methods given before operation, and if the stones were invariably single they would be very satisfactory, but it does not seem from the history of these cases, nearly 12% of which had more than one calculus, that we are justified in closing a wound made for the purpose of extracting a stone, without complete exploration of the pelvis of the kidney and the ureter by passing a full-sized ureteral bougie, or by external palpation of the ureter, or both.

NATURAL HISTORY.

Before considering the treatment of this condition it is worth while to consider what may happen without treatment. A calculus may pass into the bladder after some time, and may pass out through the urethra, or remain in the bladder to serve as a nucleus for a larger vesical stone. It is impossible to tell in what proportion of cases this occurs.

If the calculus remain in the ureter it may produce a hydronephrosis. Morris says that in 32 cases of hydronephrosis collected by Sir William Roberts a calculus was found in the ureter in 11, and in three more he considered the condition due to a calculus, although none was found. In five cases it was due to a stricture in the region of the vesical end.

The theory, advanced some time ago, that many cases of stricture of the ureter are due to the irritation produced by a previously impacted calculus, is interesting in this connection.

[6] Noble: Am. Med. Sept. 27, 1902.
[7] Kreissl: Medical Brief, St. Louis. July, 1903.

In another series of 18 cases of hydronephrosis, referred to by Morris, a calculus was found in the ureter in 11. Israel,[8] after detailing some experiments and some operative accidents, says that "clinically and experimentally a complete closure of the ureter will not produce a hydronephrosis, but a partial obstruction lasting for a long time will produce this condition."

Another result of the presence of a calculus in the ureter may be an acute pyelitis or pyelonephrosis. I have found no statistics bearing on this point, but at least 15 of these cases were operated upon for one or the other of these conditions.

The third and perhaps most serious result of letting nature take its course is complete cessation of the functions of both kidneys. Morris, in a collection of 47 cases of anuria with stone in the ureter, reports their location as follows:

Upper end of ureter	30
About middle	7
Lower end	10

He reports 9 others in which the stone was in the pelvis of the kidney.

He quotes Legueu's collection of 23 cases of anuria due to calculous obstruction of the ureter. The location of the calculus as found at autopsy was as follows:

Calculus at upper extremity of ureter	13
Calculus at some intermediate point	4
Calculus at the vesical end	6

He found 7 more with calculus in the pelvis of the kidney.

In the 21 cases of anuria which appear in the combined list of Schenck and myself, the stone was found

High up in	11 cases
About the pelvic brim in	3 cases
Low down in	4 cases
Not stated in	3 cases

These figures would indicate that the danger of anuria decreases after the calculus passes the first constriction and increases again slightly after the calculus reaches the vesical end.

Another possible result is the breaking through of the calculus into the abdominal cavity, or the retroperitoneal space, resulting, in the first case, in a general peritonitis, and, in the second case, in a retroperitoneal abscess. Two cases of the latter condition are reported.

These serious results which have occurred without surgical interference indicate that a calculus in the ureter can produce more disastrous consequences than even the frightful attacks of pain and periodic disability.

MORTALITY AFTER OPERATION.

Of these 134 cases of calculus in the ureter, 12 were relieved by proceedings which did not involve a cutting operation. The calculus was discharged through the urethra naturally or was extracted with forceps, or broken up with a lithotrite, after being pushed out of the orifice of the ureter.

[8] Israel: Chirurgische Klinik der Nierenkrankheiten.
[9] Freyer: Lancet. Aug. 29, 1903.

Of the 122 cases upon which a cutting operation was performed, 98 recovered and 23 died,— in one the result is not given,— and it has seemed interesting to ascertain the conditions preceding death in the fatal cases.

Eight were operated upon while suffering from total anuria and 3 from partial anuria, making a mortality of 11 deaths in 21 cases, or 52% operated upon for anuria.

Seven out of the 15 cases which were distinctly stated to be suffering from fever and pus in the urine at the time of operation died, making an apparent mortality of 47% in cases operated upon for pyelitis or pyelonephrosis. Probably there were more than 15 cases, but I have included only the cases in which these facts were distinctly stated.

In the 19th case the bladder was opened above the pubes and the ureteral orifice slit, opening into the general peritoneal cavity. "The patient became maniacal, passed no urine on the 12th day, died on the 13th; never had any fever, but extremely rapid pulse."

The 20th case died of uremia, and an autopsy showed a cystic degeneration of both kidneys.

The 21st case was under chloroform anesthesia nearly two hours, and showed fatty degenerated heart muscle at autopsy.

The 22d case had two hours' chloroform and ether anesthesia, and also showed fatty degenerated heart muscle at autopsy.

In the 23d case the cause and time of death are not stated. Of these 23 deaths a large proportion was unavoidable, whether the patient were operated upon or not. If we subtract the 21 cases of anuria and the 15 cases of pyelonephrosis or pyelitis, we have left 85 cases operated upon for stone in the ureter, apparently without grave complications, and in which the results are stated. In these 85 cases there were 5 deaths, giving a mortality of a little less than 6%. Even this mortality rate is higher than it will be in the future, as diagnosis will be made and operation performed before secondary changes have taken place in the kidneys and in the general system.

OPERATION.

As to the choice of operation, there are several things to consider. The transperitoneal route gives access to all parts of the ureter; it does not give opportunity for complete examination of the kidney or renal pelvis, and it does open the abdominal cavity to an extra source of infection. It has been but little used, and is partially responsible for one death. Only one writer argues in favor of this route, but neither his argument nor his figures are convincing.

On the other hand, the kidney and the whole extent of the ureter, including that portion which is in contact with the bladder, are quite as accessible extra-peritoneally as through the abdominal route.

According to the figures of these 134 cases, we may expect to find the stone within an inch of one of three definite points, but we ought not only to make sure of the removal of one stone, but to demonstrate the absence of others which might cause trouble later.

If a patient is sick enough to call for operation, and especially if operation is decided upon during the earlier attacks of colic, it seems to me that the kidney and its pelvis should be thoroughly explored, and the same incision which exposes them makes the first point of narrowing in the ureter accessible. If nothing abnormal be found through this incision, a full-sized ureteral bougie should be passed into the bladder. If obstruction be found, or if it seems desirable to follow the ureter down with the fingers, the incision may be extended as advocated by Israel, Morris and others, forward and downward to the outer border of the rectus muscle two inches above the pubes, and this incision may be carried straight through all the muscular layers down to the peritoneal fat in which the ureter lies. This cut is from twelve to twenty inches long, and crosses the upper half of the external oblique and upper two-thirds of the internal oblique and transversalis at right angles to their fibers. It must weaken the wall, and in one case at least has resulted in a hernia.

The other method is to make a new incision entirely separate from the one which exposes the kidney. This incision should correspond to the lower end of the long cut before described, and the center of the incision should come over the point where the ureter crosses the iliac artery.

After going through the skin the muscular layers can be separated by dissection between their fibers, and the ureter can be identified by gently twitching it from above. Once found, it is easily separated from the peritoneum, and the fingers passed through the upper incision can meet the fingers passed in through the lower. The ureter can now be traced along the wall of the pelvis and down to the point where it enters the bladder wall.

Some writers advise pushing the stone down into the bladder, but the small size of this constriction as compared with the upper isthmuses makes this suggestion difficult if not dangerous to carry out unless the orifice be already dilated. There is so little danger in taking the calculus through the ureteral wall that it seems wiser to remove it directly, with as little manipulation as possible, provided it cannot be easily pushed up to the most accessible point.

Extra-peritoneal ureterotomy has been done 34 times, with five deaths. Three of the five were suffering from anuria when operated; one showed cystic kidneys at autopsy; and the fifth had a dilated and fatty heart.

CONCLUSIONS.

Intermittent pain on one side, with varying amounts of red blood in the urine, are constant symptoms of stone in the ureter.

Though the best means of locating stones, the x-ray cannot yet give evidence *sufficient in itself*

to warrant us in operating or refusing to operate on certain cases.

If a calculus starts from kidney to bladder, it is likely to catch within an inch of one of three places, all of which are accessible to the surgeon through extra-peritoneal openings.

A single calculus is the rule, but the exception occurs, according to these cases, about once in eight times.

The opening in the ureter or kidney pelvis for removal of the calculus should be sutured if possible. Both sorts of suture materials have been used with equally good results, and wounds in both locations apparently heal equally well. The recovery is only delayed if sutures are not used.

A calculus in the ureter is a menace not only to health but to life, and its removal is an operation of low mortality, provided it is undertaken before secondary changes appear in the kidneys.

Loumeau. Ann. des Maladies Genito-Urinaire, p. 1165. Aug. 1, 1903.	Male 64	Previous attack colic, ending in passing stones. Hard tumor in left flank appeared after left-sided colic.	Cavity filled with 5 liters yellow colorless fluid, was found communicating with a tear in renal pelvis. Ureter catheter showed a calculus low down.		Lumbar incision. Nephrectomy, ureterectomy.	Recovery
Brewer. Annals of Surgery, 1902, vol. xxxvi, p. 780.	Male 12	Pain in right side every two or three months, often with fever—seldom vomiting.	Tumor in right flank. No disease found by urinary examination.	5 months later stone was removed from prostatic urethra.	Nephrectomy with ureterectomy to brim.	Recovery
Deaver. Annals of Surgery, 1902, vol. xxxvi, p. 94.	Male 65	Severe abdominal cramp one week before. Severe pain in right flank, testicles and pelvis, with two days of anuria.	Tenderness in region of right kidney.	Stone near bladder found at autopsy.	Lumbar nephrotomy. Drain left in kidney.	Death in 3 days from uremia.
Ferguson. J. Am. Med. Ass'n, July 5, 1903.	Male 8	Anuria, renal pain on left side 35 days after right nephrectomy.	X ray shadow 2 inches down.	Stone later removed from bladder and urethra.	Nephrotomy, stone pushed up.	Recovery
Boldt. Am. Jour. Obstet. and Dis. of Women, Dec., 1903.	Female	20 years of ill-health with intermittent pain. Tumor in left flank.	Cystoscope did not show urine coming from left ureter. Calculus in upper portion.	Stone impacted, causing complete obstruction.	Nephrotomy, stone pushed up.	Not stated.
Suarez de Mendoza. Reported by Bazy, Ann. des Maladies des Org. Gen. Urin., May, 1903, No. ix, p. 673.	Female 58	Nephritic colic every 3 or 4 months for 7 years, right side. Four attacks of colic on left side, with diminished urine. Complete anuria 11 days.	Upper end; multiple; slight tenderness over normal-sized left kidney; right enlarged and tender.	23 mm. long, and size of last phalanx of little finger.	Nephrotomy. Right kidney sutured without drain.	Recovery
Tuffier. Semaine Med., Aug. 9, 1899, p. 265.	Female 36	Renal colic, right side; loss of flesh; red and white corpuscles in urine.	Low down.		Nephrotomy. Calculus pushed into bladder by catheter.	Recovery
Jacobs. Ann. de Gyn. et d'Obstetrique, Feb., 1903.	Female 44	Crisis of pain in left pelvis sharply localized. Each attack followed by 3 or 4 months purulent urine. After attack urine became clear. Pain had existed in left pelvis over 30 years.	Hard tumor felt high up in left pelvis.	Calculus of urates and phosphates, situated 3.9 cm. below pelvic brim, 7½ cm. long, 4 cm. thick and 3½ cm. wide. Weight 44 gm.	Transperitoneal ureterotomy. Suture.	Recovery
Mannierre. Chicago Med. Recorder, March, 1899.	Female 50	Pain in right side 8–10 years. Pus and blood in urine. Mass felt in region of kidney.	Two previous operations for renal calculus and persistent fistula. Below brim.		Extra peritoneal ureterectomy, low.	Recovery
Hawkes. Annals of Surgery, 1902, vol. xxxv, p. 519.	Female 33	Pain and hematuria 3 years before, followed by passage of small calculus. Six months later symptoms were supposed to be due to a chronic nephritis. Pus and alb. in urine.	Tenderness in lower abdomen. Mass felt per vaginam posterior and to right of uterus.	Stone found near bladder by laparotomy. Weight 158 gr., 2¼ in. long.	Extra peritoneal ureterotomy. Drained from loin.	Recovery
Freyer. Lancet, Aug. 29, 1903, p. 585.	Male 28	Hematuria, with recurring renal colic for 14 months, left side.	2 inches below kidney.	Size of date-stone.	Ureterotomy. No suture.	Recovery
Elliot.	Female 30	Renal colic, followed by hematuria next day.	Resistance—tenderness in right flank. X-ray shadow.	Stone 9x7x4 mm.	Lumbar ureterotomy. Stone felt 2 in. down. Ureter dilated above.	Death 8th day from uremia. Both kidneys cystic.
Noble. American Medicine, Sept. 27, 1902.	Male 35	Colic 2 years; blood in urine; pain in left kidney, testicle, bladder.	Below pelvic brim. X-ray shadow.		Iliac ureterotomy. Suture.	Recovery
Freyer. Lancet, Aug. 29, 1903, p. 585.	Female 18	Left renal colic with hematuria 18 months.	Para vesical; felt per vaginam.		Iliac ureterotomy. Silk suture.	Recovery
Young. Annals of Surgery, 1903, vol. xxxvii, No. 5, p. 704.	Male 25	Dull ache with times of acute colic, always on right side, for five years. Previous passage of calculus.	No tenderness; no tumor; less urea from right kidney; obstruction to ureteral catheter; x-ray shadow.	Stone 8x4 mm., pushed up from juxta vesical to iliac portion.	Iliac ureterotomy. Suture.	Recovery

	Sex and Age.	CHIEF SYMPTOMS.	Situation—How Recognized.	Character of Stone.	OPERATION.	RESULT.
Legueu. Bull. et Memoirs de la Soc. de Chirurgie de Paris, 1902, vol. xxviii, p. 1132	Female 37	Intermittent colic for 7 years with hematuria. Urine clear in the intervals. Left kidney and lower ureter tender.	Lumbar nephrectomy. Stone felt in pelvic part of ureter.		15 days later iliac ureterotomy. Stone close to bladder.	Recovery
Tenney.	Female 36	Recurring pain, recognized as renal colic, for 2 years. 10 years previously double ovariotomy.	Microscopic blood in urine, tenderness over lower end of ureter. Intermittent hydro-nephrosis.	Stone just below pelvic brim on left side. Stone rough, 10x8x5 mm.	Lumbar and iliac incisions. Stone pushed up and removed through pelvis of kidney. Suture.	Recovery
Stimson. Annals of Surgery, 1902, vol. xxxv, p. 518.	Female	Severe pain in lower part of abdomen.	Nodule felt in roof of vagina, apparently calculus in left ureter.	Small, slender stone, probably branched.	Suprapubic cystotomy and ureterotomy.	Recovery
Freyer. Lancet, Aug. 29, 1903, p. 585.	Male 43	Left renal colic, hematuria, frequent urination.	Cystoscope showed protrusion of left ureter.		Suprapubic cystotomy.	Recovery
Bishop. Edinboro' Med. Journal, 1899, i, p. 47.	Male 13	Vesical symptoms.	Projecting into bladder. Felt with stone searcher.		Suprapubic cystotomy.	Recovery
Newman. British Med. Jour., April 21, 1900.	Male 35	Colic for 3 years. Blood in urine.	Mass seen to project into the bladder. Cystoscope.		Suprapubic cystotomy.	Recovery
Newman. British Med. Jour., April 21, 1900.	Male 54	Pain in side and bladder. Blood in urine.	Mass projected into bladder. Cystoscope.		Suprapubic cystotomy.	Recovery
Le Filliatre. Ann. des Maladies des Organes Genito Urinaire, Feb. 15, 1903, p. 313.	Male 50	Vesical symptoms, pain, hematuria, pyuria.	Vesical and urethral stone found with metallic sound. Both removed by suprapubic cut.	Two weeks later more pain, and a second suprapubic section found a calculus 3½ cm. long, 3½ cm. wide.	Suprapubic cystotomy.	Recovery
Noble. American Medicine, Sept. 27, 1902.	Female 59	Frequent and painful urination for 9 years; blood and pus in urine.	Mass felt per vaginam near left ureteral orifice.		Suprapubic section ureteral orifice slit.	Recovery
Freyer. Lancet, Aug. 29, 1903.	Female 42	Left renal colic 2 weeks.	Felt per vaginam. Left ureteral orifice projecting.		Vaginal ureterotomy. No suture.	Recovery
Morris. Surg. Diseases of Kidney and Ureter, 1901, vol. ii, p. 470.	Female 28		Two inches above orifice left ureter. Vaginal touch.	Size of hazelnut, ends faceted.	Para sacral incision.	Recovery
Morris. Surg. Diseases of Kidney and Ureter, 1901, vol. ii, p. 470.	Female		Kidney and upper part of ureter previously removed for calculus disease.	Four calculi, each larger than dice.	Para sacral incision.	Recovery Died 4 months later probably from calculus disease of other kidney.
Wilcox. N. A. Jour. Hom., July, p. 428.	Male 47	Left renal pain.	X-ray shadow 2 inches above bladder.	Abdominal exploration showed nothing.	Stone pushed into bladder after locating the ureter extra peritoneally	Recovery
Newman. British Med. Jour., Apr. 21, 1900.	Female 26	Pain on right, blood in urinary sediment.	Orifice right ureter, red and projecting into bladder. Cystoscope.		Dilatation ureteral orifice per urethram. Stone 1 in. up.	Recovery
Newman. British Med. Jour., Apr. 21, 1900.	Female 21	Pain in back intermittent, hydro-nephrosis left side.	Probably at pelvic brim.	Size of lentil.	Massage t. i. d. for 9 days. Calculus passed into bladder.	Recovery
Thompson.	Female 27	Pain in left side, paroxysmal in character for several months.	Blood and occasional pus in urine.	Size of beechnut.	Kidney and pelvis thoroughly explored; capsule slit; ureter not carefully examined. Stone passed 20 mos. later per urethram.	Recovery
Perkins. Denver Med. Times, 1902, p. 481.	Male 22		Mass about right kidney found by laparotomy.	Stone ⅜x¾ in. passed later itself.	Lumbar nephrotomy. Stone passed after some weeks per urethram.	Recovery
Cabot. Ann. of Surgery, Oct., 1903, p. 503.	Male 57	15 years of intermittent pain in right lumbar region, extending to right groin — with blood in urine. 2 yrs. intermittent pain on left.	Probably low down. Had passed small stones. X-ray showed nothing. Anuria.	Three small stones, the largest crushed and evacuated later from bladder.	Lumbar nephrotomy, ureter stripped downwards; nothing found, but anuria was relieved and stones passed later.	Recovery

Clinical Department.

DECAPSULATION OF THE KIDNEYS.[1]

BY EDWARD REYNOLDS, M.D., BOSTON, MASS.

MY experience with this operation is still so limited that I have felt unwilling to publish it in any formal way, or to make any attempt to draw definite conclusions from it, but I am very glad to take this opportunity of reporting my cases as a contribution to a collective investigation.

My experience has been limited to four cases by my belief that, in applying a new and comparatively untried operation to clinical work, we are bound to be exceedingly careful in the selection of cases, and to recommend it only to the few patients to whose circumstances we believe it to be peculiarly applicable; but small as the number of cases is, they may be of some interest, from the fact that they were all operated upon at a comparatively early stage of the disease, that they were all subjected to careful study by segregation of the urines with ureteral catheters, both before and after operation, and that in three of them I am able to make a definite pathological report of the condition of the kidney, at the time of operation, from specimens taken during its performance. All four recovered, two may be called cured, and one relieved, while one is probably unrelieved.

I have been guided by a somewhat different theory of the operation from that advanced by Dr. Edebohls,[2] and have accordingly adopted a somewhat different method in its performance.

Most surgeons who are doing renal surgery have had more than once the unpleasant experience of cutting down upon, and perhaps into, a painful kidney to find it entirely normal, and most of us have had the pleasant experience of finding that in the great majority, if not all of these cases, the exploratory incision was followed by symptomatic relief. Some seven years ago I noticed that when such an exploratory incision was carried through the capsule and into the substance of the kidney, the edges of the capsule usually retracted widely, leaving a portion of the kidney surface exposed, as though the organ were too large for its capsule, *i.e.*, were subjected to tension by an overtight capsule; and I then came to the purely theoretical conclusion that the relief of renal pain by exploratory incision on to a kidney was probably due, first, to the separation of the capsule from painful adhesions to surrounding tissues; second, to the probable freeing of obstructed tubules by the handling and squeezing of the organ during the operation; and third, and to my mind most important, by the relief of tension due to the enlargement of the capsule after an incision in it, and hence that multiple incisions of the capsule might be indicated in renal pain. Further, my experience in renal surgery for other lesions has led me to notice (notably in tuberculosis) that when one kidney has been the seat of disease, the urine from the other has almost invariably shown casts and other evidences of irritation (I have studied all my renal cases by segregation of the urines with the ureteral catheters), and that when the affected kidney has been removed, the casts and other abnormal elements rapidly disappeared from the remaining kidney. This led to the reflection that since we know nephritis to be usually the result of an infection from above, occurring during the elimination of bacteria from the circulation by the kidneys, it is inherently probable that in the early stages, at all events, of chronic disease, the affection will be either limited to, or predominant in, one kidney, and to believe from analogy that if in such cases the worse kidney were relieved by operation, the recovery of the other would probably follow. These theoretical considerations have led to my operating, in the first place, by slashing the capsule in parallel lines rather than decapsulating it, and, second, to my having operated in each case on one kidney only, believing, first, that the patient thus incurred less danger and far less discomfort during convalescence, considerations of prime importance in operating upon cases in the early stages of the disease; second, that there was a probability of obtaining as much benefit from this procedure as from the double operation; and, third, that if the case were relieved, but not cured, by this method, it was a simple matter to operate upon the second kidney later. (It is interesting to note that in two of my four cases the disease was apparently unilateral and that both have been wholly relieved and restored to health, even if it is premature to call them permanently cured.) In three of the four cases I have removed a narrow slice of kidney substance during the operation and subjected it to microscopical examination, in the belief that the knowledge so obtained would be of the utmost value in determining the subsequent treatment and prognosis of the case, as well as in settling the question as to whether the other kidney should, or should not, be subsequently operated upon.

I will not trouble you with prolonged reports of my cases, but will report in each only the important features.

CASE I. Mrs. E., thirty-five; married. Father died heart and Bright's disease; mother, of sepsis; two sisters both well. Thin, in weak muscular condition, unable to work for two years, frequent headaches and disturbed vision, occasional edema of ankles, some frequency of urination, occasionally accompanied by pain. Oct. 21, 1902. Whole urine before operation: normal color, slightly turbid, acid, 1027, albumin slightest possible trace, urea 1.13%, sediment — much vaginal epithelium, some brown granular casts, some hyalin casts, some blood.

Catheter specimens: Left: One-third less in amount than in right, dark and smoky, brown granular casts, much normal blood, many epithelium cells, probably ureteral, rare hyalin cast. Right: Normal color, much normal blood and ureteral epithelium, no casts.

[1] Read at the Annual Meeting of the Suffolk District Medical Society, October 31, 1903.

[2] Compare with Dr. Gifford's experimental results.

Operation Oct. 30, 1902. Left kidney exposed, freed, capsule slashed, organ stitched in position and wound closed; no pathological specimen taken. Nov. 7. Rare granular cast. Nov. 11. No casts seen, slightest possible trace of albumin. Feb. 24. Four months — one hyalin cast found, albumin absent. March 6. No casts, no albumin. This patient has gained color, flesh and strength, and to-day (just one year after operation) seems wholly well; working.

Case II. Mrs. N., seen with Dr. P. M. Smith and referred to the Free Hospital for Women for operation. Thirty; married. Grandfather died of Bright's disease, one brother of phthisis twelve years ago. After diphtheria a year and a half ago she noticed an increase in frequency of urination and a great increase in the total amount of urine passed. She became subject to great general edema, vertigo and disturbed vision. These symptoms improved for a time, but recurred after the lapse of a few months. For seven months she has had a staggering gait and has been mostly in bed, with mild uremic symptoms.

Feb. 12, 1903. Urine on entrance: Total amount 1470 cc., normal color, flocculent sediment, urea 1.13%, specific gravity 1013, acid, total urea 16½ gm., sugar absent, albumin ¼ of 1%, indoxyl minus, total solids 44½ gm., sediment — vaginal epithelium, some pus, normal and abnormal blood, some free fat, occasional bladder cell, a few hyalin casts with fat, a few small round cells probably renal.

Diagnosis: Diffuse nephritis. Catheter specimens show both kidneys to be equally affected. Operation Feb. 26, 1903. Left kidney was selected for operation as a matter of convenience, the two organs being equally affected. The kidney was cut down upon, freed, the capsule slashed, the organ stitched in position. A thin section removed from the substance of the organ along the line of one of the slashes in the capsule was examined pathologically, and reported on as follows: Section from cortex shows everywhere a great infiltration of round cells and beginning connective tissue formations. The tubules have in great part disappeared, or are very much compressed by the invading connective tissue formation. In places there are round areas of round cells like local foci of inflammation. In some places convoluted tubules can be seen which show marked cloudy swelling. Many casts can be seen. The blood vessels show thickened walls. The glomeruli show hyalin change, many of them having become only shrunken hyalin balls. The interstitial element predominates. Diagnosis: Interstitial nephritis. It will be seen that this kidney was in quite an advanced stage of degeneration. Considerable increase in number of casts shown on day after operation. Amount of albumin becomes daily less.

March 4. 1/16 of 1%. March 10. Both kidneys same — 1/16 of 1%. The amount of albumin then decreases and averages from 1/16 to 1/16. Last report, May 15, albumin 1/16 of 1%, rare hyalin casts, with very small amount of fat seen. At the end of June she was pale and weak, but had no uremic symptoms. She has been lost sight of since. There appears to me to be every prospect that with long continuous care of her general health she may eventually recover. I have, however, classed her as relieved. It will be noticed that the kidneys were apparently equally affected and that the relief of symptoms followed a unilateral operation.

Case III. R. F., sixteen; single. Father, mother and two brothers all well. Patient at the Free Hospital for Women. Has been for a long time under treatment in the medical wards of one of our large hospitals and was discharged unrelieved. Is pale and weak, incapable of work or other exertion. Has much general edema, increased on any exertion or indiscretions of diet. Is subject to headaches, but has no other well-marked uremic symptoms. Appears to be a case in which the constitutional debility outweighs all renal symptoms and seems unfavorable for operation, but as the prognosis seems entirely unfavorable without it, and she is eager to have it done, is at least worthy of study.

Nov. 27, 1902. Examination of urine for a period of about two weeks upon entrance showed a great variation, depending somewhat upon diet, exercise, etc. Daily amount varied from 16 oz., with a specific gravity of 1024, to 79 oz. and a specific gravity of 1005. Total solids did not show a great variation, averaging about 30 gm. Albumin varied from a very slight trace to ¼ of 1%. Hyalin and finely granular casts, with fat adherent, varied greatly in number, being affected to a certain extent by diet.

Nov. 20, 1902. Ureteral catheter specimens showed both kidneys equally affected. Further trials with diet and rest showed more marked effect on condition of urine.

Operated upon December, 1902. Up to the time of operation the urine averaged 120 oz. daily and reached 165 per diem as its highest mark. The left kidney was selected as a matter of convenience, was freed and capsule slashed, and the organ stitched in position. Immediately after operation the amount of urine fell to 40 oz., from which it gradually increased. For two days after operation a very large number of hyalin casts, with fat adherent, were seen. For a month albumin continued about ½ of 1%, number of casts gradually growing less.

Jan. 8. After much ureteral pain patient passed a fibrinous membrane, containing leucocytes and cells, probably from the ureter. During January casts very much less, some days not appearing at all, albumin averaging ⅛ of 1% to 1/16.

February. Casts entirely disappear and reappear again the last of the month in considerable numbers, when the patient was allowed to be up. During March albumin showed great variation, varying from 1/16 to ⅛ of 1%. Jan. 20, 1903. Urine passed at home, patient up and about and probably living on ordinary home diet, showed condition of urine same as on entrance to hospital. Feb. 3, 1903. A specimen of urine was sent to Dr. H. S. Hewes, in whose care she had been about a year before, and he wrote saying that if he were to see this urine for the first time he should regard it as a case of interstitial nephritis, but in connection with the history would say that it suggested a general interstitial disease, with parenchymatous areas relieved by operation. The specimen removed showed under the microscope: "Frozen section. There is everywhere cloudy swelling and degeneration of the epithelium in the tubules. Casts can be seen in some of the tubules. In places a slight increase in the interstitial tissue can be made out. There is also some passive congestion. The glomeruli are not maredly changed, though more cellular than normal. Preliminary diagnosis — parenchymatous degeneration."

From that time to this the patient's condition has varied up and down, and she is to-day not in very different condition from that of a year ago before operation. The specimen sent to Dr. Hewes on June 20, 1903, showed both parenchymatous and interstitial disease present, and specimens examined by us since then have varied from absolutely no evidence of pathological up to the evidence of both forms of disease.

The operation cannot be regarded as having benefited the patient's condition, but it is fair to say that she was for a time much better, that she is unintelligent, and has persisted in living in a most unhygienic way.

CASE IV. Although it will be seen this case is not typically a nephritis, its history is so interesting in this connection that I have no hesitation in including it.

Mrs. B. C. Seen with Dr. C. A. Atwood of Taunton, Mass. Thirty-one. Has never been very strong since an attack of scarlatina in girlhood, but presented no renal symptomatology until she was attacked by hematuria in 1893. From this time on the hemorrhages recurred irregularly, but with increasing frequency, at first accompanied by pain on the right side, later by pain referred sometimes to one side, sometimes to the other. She became weak, thin, pale, was troubled with urinary frequency and more or less urinary pain. She had been supposed before I saw her to have tubercular kidneys, the diagnosis having been made by the discovery of bacilli in the sediment by a distinguished urinologist. Subsequent investigation on his part, however, convinced him that the bacilli found were probably imperfectly decolorized smegma bacilli, and several injections of the sediment of the urine into guinea pigs, with negative result, entirely disposed of the tubercular theory. The patient was examined with the ureteral catheters a number of times, both during the attacks and in the intervals, and I more than once saw blood flowing steadily from the ureteral orifice on the side on which the patient was complaining of pain. It became apparent that her symptoms gave definite evidence of which kidney was at the moment attacked. The urinary sediment always showed abundant brown granular casts, much organized debris and a great amount of crystals of oxalate of lime on the right side. The same elements were always present but in less degree in the specimen from the left kidney. In March, 1898, after three months of observation, I dilated three strictures, which had been found to exist in the right ureter, but the patient obtained no benefit, except from somewhat decreased pain in urination. Six months later, the symptoms continuing and the patient's general condition growing worse, I cut down (Oct. 28, 1898) on the right kidney, freed it from its bed, brought it to the surface, palpated it thoroughly, subjecting it to a great deal of manipulation and squeezing in the process, slashed the capsule in several places, and, at the request of her husband, himself a surgeon and present at the operation, removed a slice from the kidney for microscopical examination. It was examined by Dr. Wm. F. Whitney, whose opinion was that it showed merely the presence of granular degeneration. The patient made a rapid and favorable recovery, but three weeks after the operation, when about ready to go home, had a severe attack of pain on the right (the operated) side, terminating with the discharge of a very large amount of organized debris, resembling partially decomposed renal substance, on the exact nature of which no microscopist whom I consulted was willing to commit himself. The discharge of this substance was followed by a considerable attack of hematuria, lasting some hours. Following the operation the patient rapidly gained health and strength, and has to this day (just five years) led an unusually active and energetic life in the possession of apparently the best of health, presenting a most marked contrast to the increasing semi-invalidism which had been her condition before operation, and although four years from the date of operation she had a slight attack of hematuria, with pain referred to the left side, this has not been repeated and has been followed by no decrease of her excellent health. While she cannot be reported as finally cured, the operation has certainly yielded a most gratifying result of five years' duration, and it is also of interest that the single renal symptom which has occurred since operation was referred to the kidney which has not been operated upon, and which previous to operation had been making trouble at frequent intervals.[3]

In summing up my experience, I am led to the following rather tentative conclusions:

(1) We must admit that our present knowledge of the pathological physiology of renal disease is still defective, but we are justified in believing that nephritis has, as a rule, an infective origin, and probably that the defective renal drainage, due to swelling of the organ within a rigid capsule, plays a part in maintaining the disease.

(2) That the cases in which general uremic symptoms are more prominent than the physical signs obtained on the examination of the urine are unpromising cases for operation.

(3) That where the urinary signs and constitutional depression outweigh the distinctly uremic general symptoms, we may regard the cases as favorable for operation.

(4) That where one kidney is mainly or predominatingly affected, a unilateral operation upon that kidney offers an excellent chance of prolonged improvement in health, if not, indeed of ultimate cure.

(5) In women, in whom ureteral catheterization involves little trauma and less risk, all cases of chronic nephritis should be subjected to ureteral catheterization and the unilateral ones selected for operation.

This last of my conclusions is perhaps less tentative in its status than the others and may bear a little amplification.

It is, *a priori*, inherently probable that in this, as in other infective diseases, the affection is likely to localize itself in one portion of the affected organ, or in one of a pair of organs; but for this point we are not obliged to depend on the inherent probabilities. We know from well-established observation that one portion of the substance of the kidney is more likely to be affected in any given case than another, and we have in the last two years accumulated a considerable number of cases in which the disease was definitely known to be localized in one kidney only. We have seen not only in these cases of mine, but in others which have been reported here to-night, and still again in others previously reported in literature, that the unilateral cases may be expected to do well after operation.

I think we may safely conclude that the ureteral catheter furnishes the only method of segregation of the urine which can, as yet, at all events, be regarded as definite. The use of

[3] A report received while this was in press tells of several recent hemorrhages but good general health.

ureteral catheterization in men can hardly yet be considered to have been established as an easy and unimportant examination, but in women the use of the ureteral catheters is exceedingly easy, and may, I think, fairly be said to be non-injurious, since in a very large series of such catheterizations I have never seen an untoward symptom result.

I think, then, we may fairly conclude that in the present state of our knowledge every case of nephritis in a woman should be subjected to ureteral catheterization as soon as recognized, and that in any unilateral case in which the normal state of health is being decidedly and progressively lowered, we may conscientiously recommend the operation as affording a fairly definite prospect of relief to an otherwise incurable condition.

Medical Progress.

RECENT PROGRESS IN GENITO-URINARY SURGERY.

BY F. S. WATSON, M.D., AND PAUL THORNDIKE, M.D.

(Concluded from No. 4, p. 96.)

A TABLE FOR KIDNEY OPERATIONS.

J. H. CUNNINGHAM, JR.,[17] describes a new table for operations upon the kidney and illustrates the use of such a table by three photographs. The contrivance is cheap and can be placed upon any operating table.

CATHETER STERILIZATION.

Goldberg[18] experimented with catheters infected by soaking them in purulent urine for one or more hours. Fluid antiseptics proved entirely unreliable, but a current of steam at 100° C. was effective. Sterilization was always readily and easily accomplished by boiling in water 5 to 10 minutes in a vessel longer than the instruments. He recommends soap and water washing before boiling.

Nancrede and Hutchings[19] find that the larger the size of the instrument the quicker the sterilization, and that preliminary flushing under a water tap lessens the time required for boiling by three quarters. Formaline vapor needs twenty-four hours in order to sterilize. English webbing catheters can be boiled indefinitely in a saturated solution of ammonium sulphate, provided the instruments are kept from contact with the bottom of the vessel. Ten minutes is not too long a time to boil the smaller instruments.

Casper[20] recommends a mixture of glycerine, water and tragacanth, with 1-500 mercury oxycyanate as an ideal antiseptic lubricant for catheters and sounds.

RENAL ANEURISM.

Ziegler[21] collected 19 cases of traumatic and 7 cases of nontraumatic renal aneurism. In the latter cases endocarditis with embolism or atheroma of the vessels was the cause. All the cases which were not operated died, while of the 4 cases operated upon 3 recovered.

QUICK STAIN FOR THE GONOCOCCUS.

Wahl.[22]

Concentrated alcoholic sol. of auramin 2 cc.
Alcohol 95% 1.5 cc.
Concentrated alcoholic sol. of thionin 2 cc.
Concentrated aqueous sol. of methyl green 3 cc.
Water 6 cc.

This solution is ready for use at once, keeps a year, and stains the cocci dark and the other elements in the secretion, a lighter color. It acts in five to fifteen seconds.

INSTRUMENTS TO MAKE THE PROSTATE MORE ACCESSIBLE WHEN ENUCLEATING THE GLAND THROUGH THE PERINEUM.

The instrument devised by Young[23] has two blades at its distal end. It is passed into the bladder through an external perineal urethrotomy incision, with the blades closed; they are then separated in the bladder and, traction being made upon the handle of the instrument, are brought against either side of the enlarged gland and forward toward the surface of the perineum. The prostate is thereby brought within easy reach for the subsequent manipulations required for its enucleation.

The same object is sought by the instrument of Lydston,[24] which is however of different form.

CALCULUS ANURIA. ITS DIAGNOSIS AND TREATMENT.

The following are some of the points with regard to the diagnosis and treatment of the above condition dealt with by A. T. Cabot.[25] It may be the result of the gradual disorganization and destruction of the kidneys in consequence of pyelitis and pyelonephritis, caused by the irritation of the stone, or it may be brought about by the stoppage of the ureter by a stone. The latter is the form properly known as calculous anuria. This condition is to be distinguished from other forms of anuria by its sudden onset and the absence of uremic symptoms in many cases. Sometimes death supervenes without uremic symptoms having occurred. The duration is, in some instances, very long. A case of Morris is quoted in which the anuria persisted for twenty days. Sometimes the condition is intermittent. Polyuria follows the cessation of the attack. When both ureters are blocked, the obstruction on one of the sides is usually of long duration, and the kidney on that side is already practically destroyed. In the other cases fatal suppression of urine has been known to follow

[25] Ibid., October, 1903.

upon the stoppage of one ureter, the kidney of the opposite one being comparatively healthy.

Morris does not report any cases of recovery in which the latter was brought about by the spontaneous escape of the stone into the bladder. The writer however suggests that the cessation of the anuria was due, in one of his cases, to the expulsion of calculi, very possibly brought about by manipulation of the abdomen in the renal region, and quotes two further cases in which spontaneous expulsion was followed by recovery. The reason given for the infrequency of spontaneous expulsion of the calculus in these cases is the absence of pressure from behind it, due to the completeness of the anuria.

In a series of 104 cases, 56 collected by Legueu and 48 by Morris,— treated expectantly,—there were but 26 recoveries — a mortality of from 72% to 80% following this plan of treatment. In many cases pain is absent, or slight and of very short duration. The article contains other points of interest and the reports of three of the writer's own cases.

THE REMOVAL, AFTER SUPRAPUBIC CYSTOTOMY, OF THE PROSTATE AND THE PROSTATIC URETHRA FOR SENILE ENLARGEMENT OF THE PROSTATE, WITH A SERIES OF TWELVE CASES.

The operation above mentioned is described thus by Moynihan.[26] Previous to opening the bladder 10 or 12 oz. of 1% carbolic acid solution is introduced into it. The viscus is then opened above the pubes, the left forefinger is introduced. A stay suture is passed through either edge of the bladder incision, and the latter are attached to the abdominal wound by them. These sutures are allowed to remain *in situ* for four days.

A snip is made into the mucous membrane of the trigone immediately behind the internal meatus of the urethra with a pair of sharp-pointed scissors. The tip of the finger enlarges this opening. Two fingers of the right hand are then passed into the rectum, the thumb is pressed into the perineum, and the prostate firmly held, while the left forefinger begins the stripping of the gland. The opening in the mucous membrane is enlarged until it completely encircles the internal meatus. The surface of the lobes is rapidly cleared, and finally the prostatic urethra is torn across at its junction with the membranous urethra, after the prostate has been entirely freed elsewhere. The enucleation is, as a rule, performed in from two to five minutes. The prostate, together with the prostatic urethra, is removed in one mass through the suprapubic incision. There follows the description of the twelve cases in which the author has performed this operation.

RESECTION OF URETHRAL STRICTURE.

Therman[27] describes four cases of stricture treated in this manner. In the first the stricture had originated in an injury of the urethra in its anterior portion seven years previously. The caliber of the stricture was 13 (French). Behind it was a diverticulum communicating with the urethra the size of a hen's egg. The stricture was resected, and a urethroplastic operation was done. The result was wholly satisfactory. In the second case a stricture admitting No. 21 (French) bougie was situated in the bulbous urethra. In this instance also it was of traumatic nature, and resection likewise yielded satisfactory results. The third patient had a stricture of No. 8 caliber in the perineal urethra, the formation of which was associated with a suppurative process of the urethra sometime previous to the operation. Resection and end-to-end suture secured a good result. The last case was one in which the operation was done six weeks after the receipt of an injury of the urethra by bullet wound, which resulted in a destruction of half an inch of the canal. Urethroraphy was followed by first intention of the wound and excellent recovery.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY,

ANNUAL MEETING, OCT. 31, 1903.

DR. F. G. BALCH and DR. J. C. HUBBARD reported cases of

DECAPSULATION OF THE KIDNEY.

DR. A. T. CABOT: It is interesting to consider in the first place what influence for the better the operation exerts on the kidney.

Four ways occur to me in which the interference may exert a beneficial influence on the inflamed organ.

In the first place, the trauma of the tissues overlying the kidney acts in the way of a counter-irritant, and the local blood-letting doubtless assists somewhat in enhancing this effect.

Secondly, the manipulations necessary to free the kidney from surrounding attachments, and to bring it outside the body, produce a vigorous kneeding and massage of the organ. The kidney is wrung out like a sponge. May not this massage squeeze the casts and debris out of the tubules and thus clear the kidney of some of the clogging material that interferes with its function? I am inclined to think that we may find in this a partial explanation of the shower of casts which has been spoken of as appearing for the first day or two after operations.

Thirdly, we may have an improvement of the blood supply through the new connective tissue thrown out during the formation of a new capsule. It is in this way that Dr. Edebohls believes that the principal benefit of the operation is obtained; and Dr. Gifford's observations seem to show that for a time during the healing process some effect of this sort may be temporarily

obtained. That this, however, is not the only way in which the benefit is produced, is shown by the speedy improvement noticed in some of the cases; an improvement showing itself before we can suppose that any considerable collateral circulation has had time to form.

Lastly, we come to what I believe to be one of the most important effects of these operations upon the kidney capsule. This is by the relief of tension both by the splitting and removal of the capsule and by the direct blood-letting of the organ. This effect is produced when the capsule is incised without being stripped off, and it is also obtained in these cases where by a straight cut an opening into the capsule is obtained. Indeed, I have seen a very immediate relief of serious renal symptoms following an exploration with an aspirating needle, where a dram or two of urine was obtained, and where the operation consisted of a number of punctures through the kidney in various directions without incising the skin. The relief in these cases was as immediate as is sometimes seen by puncture of an inflamed testis, and I can only account for it by the relief of tension afforded by these numerous punctures through the capsule.

Now, in regard to the attitude which we ought to bear towards this operation. Every man who is doing much kidney surgery knows how often an acute or sub-acute inflammation of the kidney is influenced for the better by cutting down upon that organ. This improvement is noted sometimes in cases where the capsule is not split, or is opened only for a short distance. Being aware of this benefit obtained in acute cases, the next step made by many operators, but most strongly urged by Dr. Edebohls, was to apply this same treatment to chronic cases of kidney inflammation; to the cases, in short, grouped under the head of Bright's disease.

The cases enumerated this evening show that the operation thus applied is not dangerous, and that many cases show some improvement after it. It is to be remembered that in these operations, as in many others of doubtful utility, operators have thus far felt obliged to confine their interference to desperate cases. If, now, these cases in which the kidneys are already profoundly disorganized are helped in an appreciable degree by the operation, is it not reasonable to hope that by using it earlier, before the kidneys are changed beyond recovery, a restoration to something like a normal condition may be obtained? If this view is correct, and we come to believe that the operation has a power for good, and that in order to do good it should be applied while the kidneys have some possibility of recuperation left, it is plain that we must endeavor to study our cases so carefully as to be able to judge early whether a given case is likely to recover without operation or not, and if we decide that on the whole it is not likely to so recover, I feel that we are then justified in using this operation, which applied thus early in the disease would have practically no danger, and might have the greatest power for good.

Dr. F. C. Shattuck: One of Edebohl's statements was, to me at least, startling. The inspection of the living kidney showed Bright's disease to be, in some cases during a part of its course, a unilateral process. This contravenes post-mortem experience as well as our notions of the origin of Bright's disease in some general, usually toxic, influence. It is the rule that the early lesions of a generic poison are practically symmetrical. Pneumonia, it is true, is an exception. Further evidence on this point seems very desirable. As far as the cases reported to-night go, Edebohl's statement does not seem to be borne out.

I had hoped to get more enlightenment this evening than I have — to be enabled to estimate more closely the value of decapsulation for Bright's disease. The cases of distinct improvement reported this evening are few, and anybody of fairly long and large experience must recall cases alike of diffuse and interstitial nephritis which, after tedious and patient waiting, for no very clearly assignable cause, have turned the corner, made and maintained for years great improvement—amounting, indeed, to the disappearance of symptoms and the ability to lead a practically normal life.

That decapsulation is followed by this result in a larger proportion of cases than occurs without it remains to be proved.

More or less passive observation is harder to practice than active interference in these days of cleanly surgery. And yet it may be the wiser course.

Personally I do not as yet feel warranted in advising the operation in a patient who is fairly comfortable and apparently holding his own.

Dr. J. C. Munro said that he was disappointed in the final results of his cases, but felt that the operation was worth while, considering the desperate nature of the disease. It is important, if surgical aid is to be sought, that the cases should not be turned over to the surgeon when practically moribund, as was unfortunately the state of affairs in at least one of his cases. If, however, as Dr. Shattuck has suggested, the lives of a small proportion of apparently hopeless cases can for some reason or other be prolonged by medical treatment to as satisfactory a degree as by decapsulation, then it is questionable whether the operation is after all justifiable. He was not aware, however, that other physicians had had equally good success.

In reading a recent article by Dr. Thomson of New York, a very suggestive query was forced upon the speaker's mind, which he would like to make to any physiologist or internist present. Dr. Thomson spoke of the similarity between the effects on the circulatory system, etc., as caused by contracted kidneys and by the administration of adrenalin. On this basis it occurred to the speaker that possibly the beneficial effects from decapsulation might come from the disturbance inflicted upon the adrenal capsules in the efforts at delivery and decapsulation, thereby impairing their functions and lessening

the supply of their secretion to the general circulation. If this were possible or probable might not the same or better results be attained if we remove a portion of one or both capsules? He thought that this might be worth while doing in a case which would ordinarily be subject to decapsulation. He trusted that some physiologist present could enlighten him in this respect.

DR. PAUL THORNDIKE: The cases reported by Dr. Hubbard to-night have been mentioned in subsequent discussion as "unpromising." There certainly is a very marked contrast between these results and those of many other operators, but it must be realized that several of them were last-resort cases and were not fit subjects for this or any other surgical procedure. Dr. Edebohl has said that the only contra-indications for the operation are the impossibility of anesthetizing the patient and the improbability that the patient will live a month after operation, as it takes at least that length of time for improvement to take place. It seems to me that we have already considerable evidence to show that many of the most brilliant successes have also been immediate successes, and I believe the future will show that the best results will be obtained not in old last-resort cases when all else in the way of treatment has failed, but in those more recent cases where the inflammatory condition has failed to clear up under medical treatment and has persisted with enough urinary and other clinical evidence to make a distinct surgical indication. I therefore do not believe that Dr. Hubbard's series of cases should be considered as significant of the true value of decapsulation.

DR. HENRY JACKSON: If we except the brilliant results obtained in the cases reported by Balch, in which only one kidney was diseased, we find the most satisfactory progress in two cases, one reported by Balch,[1] one by Hubbard.[1] In each of these cases the probable clinical diagnosis was chronic diffuse nephritis. All acute processes as indicated by smoky urine, or blood in the sediment, could be eliminated in these two cases. From the results so far at our command in studying these cases I should be inclined not to favor operation in cases showing evidence of acute trouble. In fact, acute nephritis is especially amenable to medical treatment in most cases.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

PROCEEDINGS OF THE SIXTEENTH ANNUAL MEETING, HELD AT THE PIEDMONT HOTEL, ATLANTA, GA., DEC. 15, 16 AND 17, 1903.

(Concluded from No. 4, p. 99.)

SYMPOSIUM ON APPENDICITIS.

DR. GEO. R. DEAN, Spartansburg, S. C., read a paper in which he considered it a surgical disease, outside of the pale of the physician, and when it was once discovered operation should be done at the earliest possible moment.

[1] Boston Medical and Surgical Journal, Jan. 28, 1904.

APPENDICITIS AND ITS RELATION TO PELVIC INFLAMMATIONS.

DR. J. M. BALDY, Philadelphia, Pa., expressed himself as being unable to follow the reasoning of those who adopted the practice of removal, on the ground that the condition of adhesion implied appendicitis or future danger of this disease. He did not agree with that class of surgeons who removed the vermiform appendix as a routine practice as a prophylactic measure. He thought 95% of the mixed class were in origin cases of pelvic inflammatory disease, and the adhesion of the vermiform appendix was a mere coincidence due to inflammation of contiguous serous surfaces, as was so commonly the case of adhesion of intestines in pelvic inflammatory diseases. His experience had led him to differ from those gentlemen who held that appendicitis generated pelvic inflammatory disease, or that pelvic inflammatory disease caused appendicitis. The two diseases were rarely associated, and only then as a coincidence. He was firmly of the opinion that the one never caused the other.

RETROPERITONEAL INFECTION A RESULT OF APPENDICITIS.

In a paper on this subject, DR. I. S. STONE, Washington, D. C., said it was our plain duty in certain septic cases to investigate the retroperitoneal space with the same care as the cavity of the peritoneum. First, one should consider every delayed case with anxiety, lest there should be retroperitoneal infection. Second, one should be careful to give a guarded prognosis in every case of appendicitis ushered in by or complicated by chills or any symptoms of sepsis. Third, if operating on such cases, one should consider retroperitoneal infection as already started, and act accordingly. The discovery and proper treatment of such infection was quite as important as the usual intraperitoneal techinque.

In view of the possibilities of retroperitoneal infection, the surgeon assumed great responsibility by advising non-intervention in appendicitis, and while one would often advise delay, when he believed the lesions were strictly intraperitoneal, yet it would appear to the writer that such a course is unsafe, and should be condemned when there was reason to fear complications.

SHORT INCISION IN APPENDICITIS.

DR. ROBERT T. MORRIS, New York, said the beginner in surgery was inclined to make incisions that were too short, rendering his work more difficult and very likely incomplete. The surgeon could not do good work, particularly in abdominal surgery, if he began his work with incisions that were too short. He could not do the best work if he continued to make incisions that were too bold or too free. After one had acquired a certain amount of skill in technique, he could return to the shorter incisions, which would allow the patient to escape with the least

possible length of incision. With long incisions there was more shock, more adhesions, because the exposure of the peritoneum through a long incision excited greater inflammatory reaction, and this resulted in more peritoneal adhesions, which must be disposed of, or which might remain, to make the patient lifelong trouble. The longer the incision, the greater the danger of infection from the aërial bacteria. With long incisions the patient's general resistance was interfered with. He would make this statement, however, that the surgeon should make as long an incision as he felt was necessary, and by no means be guided by the idea that he was to conform to any length of incision. If one could allow a patient to escape with a short incision, he should do so.

THE SIGNIFICANCE AND MANAGEMENT OF PARALYSIS OF THE BOWEL.

Dr. Geo. S. Brown, Birmingham, Ala., emphasized the views held by the surgeons of the past generation, that paralysis of the bowel in the presence of inflammation of the peritoneum was to be regarded, not as a pathological condition to be combated, but rather as nature's way of allowing the plastic exudate to form adhesions, the use of which was to confine the infection to as limited a field as possible. He held that it was not the paralysis, but the over-distention of the bowel, that should be fought. By following the plan of keeping the upper uninflamed portion of the bowel quiet, until the inflammation subsided, rather than attempting the difficult or impossible feat of waking up the inflamed and paralyzed portion by the use of purgatives, he believed many or the majority of the worst cases of diffuse peritonitis with which the surgeon had to deal would be cured. This rest treatment should be applied after the offending appendix or tube had been removed, and the infected site properly treated and drained. It seemed to him that if the Ochsner plan of treatment would tide over a patient with a gangrenous appendix, such a patient would have a much better chance if the appendix were removed, and to the Ochsner treatment were added the tight abdominal binder, with water to relieve thirst, and washing out of the stomach, if there was vomiting, together with opium *ad libitum*, to relieve pain and keep down peristalsis.

In a total experience of 90 cases of appendicitis he had had 66 pus cases, 24 of which had been treated by the plan of starvation, except as to water, prolonged irrigation of the stomach before leaving the table, a tight abdominal binder and opium. Eighteen of these patients had more or less diffuse peritonitis and 12 of these were so severe that they had to be extensively disemboweled in order that adhesions could be broken up and septic material wiped away. Two only of these died. They might have recovered had they been tided over without operation, but as they were both *in extremis* at the time, probably the only thing saved would have been the reputation of the surgeon. Of five other deaths occurring in the 90 cases, two were due to subdiaphragmatic abscess rupturing into the lung, one to regurgitant vomiting due to the presence of a large quantity of castor oil in the bowel which was not washed out, and two early cases where abscesses that had already set up a diffuse peritonitis were merely incised.

SEPTIC THROMBOSIS OF THE FEMORAL VEIN FOLLOWING INFLUENZA.

Dr. D. F. Talley, Birmingham, Ala., reported a case of septic thrombosis due presumably to influenza from which the patient was recovering when the phlebitic trouble arose.

FIVE RECENT SUCCESSFUL LAPAROTOMIES FOR GUNSHOT WOUNDS OF ABDOMINAL VISCERA, INCLUDING ONE WITH TWENTY-EIGHT PERFORATIONS OF INTESTINES AND MESENTERY.

Dr. Robt. W. Johnson, Baltimore, Md., read a paper with this title. The first case was one of gunshot wound of the stomach and liver; laparotomy, with recovery. The second, a gunshot wound of the liver; laparotomy, with recovery. The third was a gunshot wound of the liver; laparotomy; recovery. The fourth was a gunshot wound of the intestine; laparotomy; recovery. The fifth case was one of gunshot wound of the intestine, in which there were 17 perforations of the gut and 11 of the mesentery. The patient was a colored man, aged seventeen. A wound from a 32-caliber ball was found in the left side, just above Poupart's ligament, which, after washing, was found to go directly into the abdominal cavity. A median incision was made below the umbilicus and the belly found to be full of blood. Through this incision the gut was drawn out on to warm towels, and seventeen perforations of the small intestine and eleven of the mesentery were successfully closed by silk Lembert sutures. The patient had no setback after the operation, and was discharged well three weeks after the injury was received.

CASES OF INTESTINAL OBSTRUCTION TREATED BY RESECTION.

Dr. W. H. Doughty, Jr., Augusta, Ga., reported three successful cases of resection of intestine for obstruction due to gangrenous umbilical hernia, volvulus and intussusception respectively. One of the cases was rather unique, in that the strangulated loop of intestine in the hernia was a part of a greater segment which had been strangulated by volvulus. The descent of the herniated coil took place shortly after the occurrence of the volvulus, and its strangulation was occasioned by the congestion which followed the latter.

The almost invariable fatality which attended the operation he attributed to the toxemia which was induced by gangrene of the intussusception. In one case, in spite of the unmistakably gangrenous patches upon the intussusception and involving even the mesentery, the patient, though far from being in a satisfactory condition, stood

the operation fairly well, rallied promptly from the depression which attended it, and recovered without interruption.

FREE GROWTHS IN THE TUNICA VAGINALIS.

DR. EDWARD A. BALLOCH, Washington, D. C., reported the case of a colored boy sixteen years of age, who came under his care in December, 1902. Family and personal histories threw no light upon the case. There was no history of injury. Present trouble began eight years before, as an enlargement in the upper part of the right of the scrotum, which continued to grow painlessly from that time onward. Examination showed a scrotum reaching nearly to the knees and measuring twenty-one inches in circumference at its largest point. Both testicles and both cords could be made out and felt normal as to size, shape and consistence. There was no fluid in the scrotum, but a peculiar gelatinous, flabby feeling of the scrotal tissue. Three separate tumors were felt in the right side of the scrotum. The growths were freely movable in relation to the cord, testis and scrotal tissues.

The diagnosis of fibroid growths in the tunica vaginalis was based partly on the history of a slow, painless growth, and absence of ulceration and fistulæ, excluding cancer, syphilis and tuberculosis, and partly on the physical characteristics of the growths, together with a keloid behind the right ear, which was interpreted as indicating a tendency to fibromatosis in the patient.

Operation, Dec. 15, 1902, showed the tunica greatly enlarged and thickened and converted into a gelatinous mass. The upper tumor ran into the inguinal canal and was attached there by a pedicle. The other two showed no distinct points of attachment. All the tumors were enucleated and the thickened tunic removed. The testicle was removed accidentally in dissecting out the tunica. The tumors weighed 38 oz. and the tunica 20 oz. The specimens were shown.

The report of the pathologist showed that the growths were soft fibromata, with areas of fatty and myxomatous degenerations. The testicle also showed areas of beginning myxomatous degeneration.

The pathology of the condition was considered briefly, the conclusion being reached that the growths had their origin in the subserous connective tissue.

Examination of the literature showed but one case at all resembling the one reported, although there were several reports of minute fibrous growths on the tunic following hydrocele treated by the injection of iodine.

DR. J. MCFADDEN GASTON, JR., Atlanta, Ga., dealt with the complications encountered in the surgical treatment of disease of the testicle.

EXTRAUTERINE PREGNANCY.

DR. T. J. CROFFORD, Memphis, Tenn., reported a case and exhibited a specimen in which the gestation sac was so thoroughly developed and so strong, that it was enucleated without the loss of any blood. The sac was completely intact all around the fetus. The speaker supposed it to be a parovarian cyst, but after the sac was slit open the fetus was discharged.

COLLOID CARCINOMA OF THE RECTUM, WITH EXCISION BY THE COMBINED VAGINAL AND INGUINAL ROUTES.

DR. J. HORACE WHITACRE, Cincinnati, Ohio, reported a case of colloid carcinoma of the rectum which presented unusual pathological and clinical features. After giving a complete history of the case and describing the operation, the author stated that his chief reason for presenting it was the unusual nature of the primary tumor. He had never before seen a carcinomatous tumor of the bowel which had developed as a hard, uniform thickening of the entire circumference of the tube. The tumor involved the wall of the rectum to almost a uniform degree for six inches of its length, and the organ was transformed into a tube that might very well be compared to a flattened lead pipe with very thick walls. The tube was very rigid and noncollapsible when in a fresh state.

A second point of interest was the strong naked eye resemblance to tuberculosis. The minute bodies which were scattered over the pelvic peritoneum could not be differentiated from miliary tubercles. Large caseous lymph nodes were found in the hollow of the sacrum. The great predominance of fibrous tissue, the uniform involvement of a long segment of the bowel and the appearance of minute nodules resembling miliary tubercles in the primary tumor of the rectum all spoke for hyperplastic tuberculosis of the bowel.

A third point was the exceedingly rapid development of the solidly carcinomatous ovarian tumors from half a dozen minute miliary metastases on the peritoneal surfaces of each. These tumors were friable and almost jellylike, as were all of the metastases, whereas the original tumor was as hard as cartilage.

PNEUMATIC RUBBER SUIT.

DR. GEO. W. CRILE, Cleveland, Ohio, said that the pneumatic suit was constructed of a double layer of specially made rubber, which, when inflated, exerted a uniform pressure upon the surface, constituting an artificial peripheral resistance. It was so constructed that one or more limbs of the abdomen might separately or in combination be subjected to pressure by inflation by means of a bicycle pump. The air valves were so adjusted that the rate of decompression might be completely controlled.

Several cases were reported showing the value of the pneumatic rubber suit in shock and collapse.

RESUSCITATION OF ANIMALS APPARENTLY DEAD.

Dr. Crile also presented a short paper on this subject, in which he gave a summary of experi-

mental data. When asphyxia caused failure of the heart and respiration, vigorous artificial respiration usually restored their function when administered within a few seconds. It was effective in an inverse ratio to the time that had elapsed; it was rarely effective after forty seconds. By the addition of saline infusion a larger proportion of animals could be resuscitated after the lapse of a little longer time. Rhythmic pressure upon the heart, either through the thorax by pressure upon the ribs over the heart or direct pressure within the thorax was also an aid. The effect of the traumatism to the heart by the direct method partially counterbalanced the benefit from this measure. Nitroglycerine, alcohol and digitalis were useless; rapidly alternating the posture, head up, then head down, was not effective. Suspending the animal head down and making rhythmical pressure upon the heart was an effective method. This method gave the brain the advantage of gravity; it provided a moderate artificial circulation as well as respiration. It could be promptly applied. The addition of saline infusion increased the effectiveness of the method. Animals apparently dead for periods up to fifteen minutes were resuscitated by the combined effect of artificial respiration, rhythmic pressure upon the heart and the infusion of adrenalin. When the blood pressure had risen to 30 or more mm. Hg., the heart began to beat and the blood pressure was rapidly restored. The return of respiration was signaled by a short, almost imperceptible movement of the diaphragm, the respiratory action becoming gradually stronger and more frequent. The conjunctival reflex returned early. Some of the experiments failed on account of too great elevation of the adrenalin bottle; some on account of an overdose of adrenalin; several were only partially successful, owing to the great dilution of the adrenalin. Adrenalin, when injected directly into the chamber or into the wall of the heart, caused fibrillar contractions, after which the heart could not be resuscitated. After final cessation of the heart, by employing manual compression of the heart and infusing adrenalin, the blood pressure could be raised even higher than the normal. Respiration in some instances was partially restored.

Experiments in which saline infusion was substituted for adrenalin, and which were unsuccessful, were promptly successful on adding adrenalin. In a patient with crushed skull, whose heart had ceased beating for nine minutes, resuscitation of the heart for thirty-one minutes by this method was made. During the operation for the elevation of the depressed bone, the patient moved his head.

Another patient apparently dead from a severe crushing of the base of the skull was partially resuscitated twenty-four minutes after the apparent death. The proofs of the apparent death were absence of respiration, absence of heart sound on stethoscopic auscultation and, as a final proof, on opening the jugular vein there was absolutely no circulation. In this case the blood pressure rose to 80 mm. at one time; voluntary respiration appeared. These evidences of vital action continued for thirty-four minutes.

OFFICERS FOR THE ENSUING YEAR.

The following officers were elected: President, DR. FLOYD W. MCRAE, Atlanta, Ga.; First Vice-President, DR. GEO. S. BROWN, Birmingham, Ala.; Second Vice-President, DR. J. SHELTON HORSLEY, Richmond, Va.; Treasurer, DR. CHAS. M. ROSSER, Dallas, Tex.; Secretary, DR. W. D. HAGGARD, Nashville, Tenn.

Birmingham, Ala., was selected as the place for holding the next annual meeting; time, Dec. 13, 14 and 15, 1904.

DR. JOHN D. S. DAVIS, Birmingham, was selected as the Chairman of the Committee of Arrangements.

The Council reported that the former action of the Association in appropriating two thousand dollars to a memorial, consisting of a ward bearing the name of the Association in the City Hospital of Birmingham be rescinded, and that in lieu thereof two thousand dollars be appropriated to the erection of a monument to the memory of Dr. W. E. B. Davis in Birmingham.

On motion of the Council, the report was adopted.

Recent Literature.

Lessons on the Eye. By FRANK L. HENDERSON, M.D. Third edition. Philadelphia: P. Blakiston's Son & Co. 1903.

This little book contains about two hundred pages of text which have been so divided into twenty-eight chapters as to provide one lesson for each week of a seven months' course. The author's intention has been to place in the hands of the undergraduate student a means of equipping himself for the later demands of a general practice, and with this purpose in view has described only the commoner conditions of the eye, relegating to the domain of post-graduate instruction ophthalmoscopy and kindred subjects. As it has reached the dignity of a third edition one may naturally infer that the book enjoys a certain popularity with the undergraduate, for whom it is intended, and therefore the author may be considered as having succeeded in his endeavor. As a rule elementary books of this character are of extremely doubtful value, for it seems safe to say that the intellect of the average medical student may safely meet the demands put upon it by any of the standard textbooks on ophthalmology of the present day. In the present instance the subject has been presented with such good judgment, and the appearance of the book is so pleasing both as regards press work and illustrations, that it is to be hoped a careful reading of this book will stimulate to farther effort along similar channels.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, FEBRUARY 4, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS

MEDICAL INVESTIGATION IN THE PHILIPPINES.

WE have recently commented on the admirable work being done under the general auspices of the government in investigating disease peculiar to the tropics. From this work it appears clear, for example, that the condition produced by Trypanosoma has been placed upon a definite basis, and has formed the starting point for a series of wide-reaching investigations on analogous affections. Such diseases may only be studied in their native habitat, and it is therefore of much importance to medicine in general that competent men may prosecute their studies on the spot rather than indirectly, and with poor facilities, at a distance. Furthermore, it is evident that the field now opening in the study of the protozoa and other similar organisms offers a peculiar opportunity for young men of capacity who find small scope for their energies at home.

We are interested in noticing in view of these facts that the Harvard Medical School, under the general supervision of Dr. W. T. Councilman, aided by a small fund contributed by several interested and generous donors, has recently sent two men of the Pathological Department, Drs. W. R. Brinckerhoff and E. E. Tyzzer, to the Philippines for the purpose of investigation into infectious diseases. It will be remembered that these physicians assisted Dr. Councilman in his work relating to smallpox, and it is primarily to study further the life history of the causative parasite of that disease that the journey has been undertaken. It is evident that means of experimentation will there be very much greater than in this country, and that the possibility at least exists of determining definitely the susceptibility of certain of the monkeys to the disease and the means of its transmission. It is, however, stated that, although this will be the main object of study, the study of tropical disease in general will also form a part of the work undertaken.

This plan of sending properly equipped medical men to the Philippines cannot be too highly commended. It is inevitable that, with the closer relationships existing between tropical and temperate countries, which the future is sure to bring forth, any knowledge leading to a clearer appreciation of the nature of diseases peculiar to warm countries will be of increasing value to the inhabitants of temperate regions. Apart, also, from this somewhat selfish point of view, it is eminently desirable that the fatal and widespread affections of the tropics should be checked. This certainly can only be done by the application of scientific knowledge already gained to the further problems which these highly infectious diseases present.

INSANITY AMONG NEGROES.

OUR attention has been called by Dr. W. F. Drewry of the Central State Hospital at Petersburg, Va., to the fact that in our issue of Jan. 7 we commented erroneously on the question of insanity in the negro. In this editorial on the "Distribution of Insanity" we made the statement that, "in the South the negroes are proverbially relatively exempt from such affections, [mental disorders]." Dr. Drewry has for many years been connected with a hospital devoted to the care of insane negroes, and is therefore eminently able to judge of the existing conditions.

In his report for 1903 Dr. Drewry states that from best available information insanity as well as tuberculosis was comparatively unknown among negroes before the war. In 1860 only 25 insane negroes were in the State Asylum at Williamsburg. Ten years later 123 negroes were reported in the state. To-day there are 1,074. In 1860 the ratio of insane negroes to the negro population was 1 to 7,000; in 1900 it was 1 to 640. From 1890 to 1900 the number of first admissions reached 1,512, being a yearly average of 125. From Oct. 1, 1900, to Oct. 1, 1903, 745 cases, or an average of 248 a year, were received. The reason given for this increase is, in general, race degeneration. During

the days of slavery it is maintained the negroes were under strict discipline, lived in clean surroundings, were subject to greater moral control, led systematic, regular lives, and in general were surrounded with conditions which conduced to both physical and mental health. Since emancipation Dr. Drewry asserts that various dissipations, vices, bad habits, irregular living, indolence, privation, etc., have led to a weakening of the negro constitution, and therefore to a natural development of disease, such as insanity and consumption.

With all due respect to Dr. Drewry's opinion, and to his unquestioned means of judging the situation, we are inclined to think he has at least put the case strongly in asserting that the difference between the negro's life before and after the war may be held wholly responsible for this increase in insanity. As we remarked in our previous editorial, the varying conditions underlying the production of mental disorders are far too subtle to permit of general statements. We are nevertheless much interested in Dr. Drewry's point of view and are glad to make the correction which he suggests regarding the prevalence of insanity in the negro population.

PARALYSING PARSIMONY.

When the appropriation of $8,000 asked for by the Massachusetts State Board of Health for the annual maintenance of its antitoxin and vaccine plant for 1904 was brought up for action in the Senate last week, the chairman of the Committee on Public Health opposed the appropriation, and moved that the latter be reduced to $6,500 — on the ground that the latter sum had been estimated as necessary for such maintenance.

This estimate was made in June, 1902, a year and a half ago, for the production of vaccine alone at a time when the Committee on Public Health succeeded in delaying action on the whole matter for another year, notwithstanding the prevalence of an epidemic of smallpox, such as had not been known for thirty years. Upon revising its estimates, and going over the whole question again, the State Board of Health found it impracticable to carry on the work of producing antitoxin and vaccine for the sum which had been named for the production of of vaccine alone.

It should be borne in mind that the board has saved to the people of the commonwealth from $75,000 to $100,000 per year by the production and free distribution of antitoxin alone.

To the physicians of the state it must appear strange that the health interests of the community are better served by the Committee on Appropriation than by a committee which was perhaps constituted for the purpose of assisting in the protection of the public health.

THE MULTIPLICATION OF SCIENTIFIC JOURNALS.

It is rare for a month to pass that men of general scientific attainment are not requested to subscribe to a new periodical. This is perhaps particularly true of journals relating to medicine, but a like activity is apparently being manifested in allied branches of science. The reason for this extraordinary multiplication of journals is not far to seek. It depends primarily upon the progress of specialism and upon the somewhat natural desire which each individual group of men has to present its researches in a form and place where they will receive the most sympathetic attention. On the medical side there is hardly a branch of medicine which in any way may lay claim to the title of a specialty which has not its own organ. In one sense this is no doubt a step in advance, but we can easily see that this continual multiplication of journals will in time lead to a reaction.

In the first place the greater the number of journals the less the number of subscribers, and the more demand for an independent fund by which they may be supported. A considerable number of journals is already independent in this respect, and may continue to publish papers irrespective of any possibility of adequate financial return. Others are not so fortunately placed, and the constant and somewhat wearisome appeal for support as a duty which we owe to science in general is becoming a trifle obnoxious.

A further difficulty which every periodical now has to face, as never before, is the question of the reproduction of photographs and drawings, often in colors of most elaborate character. Here, again, a reaction is inevitable. We have been interested, for example, in the last journal which it is proposed to launch, a *Journal of Zoölogy*, to note that in the prospectus it is stated that illustrations designed for publication be made as simple as possible and colors be avoided unless absolutely necessary. We have no inclination or capacity for prophecy, but nevertheless we are inclined to think that a greater

concentration of effort in a few journals, at least for the present, and less dissipation of energy in many would conduce to our greater scientific health.

MEDICAL NOTES.

THE BALTIMORE TUBERCULOSIS EXHIBITION. — During the past week a Tuberculosis Exhibition has been held in Baltimore in McCoy Hall, which excited much interest.

TYPHOID FEVER AT COLUMBUS, OHIO. — Since Jan. 1 nearly 600 cases of typhoid fever have been reported from Columbus, Ohio. The source of the disease is claimed to be contamination of water.

BEQUEST TO JOHNS HOPKINS HOSPITAL. — It is reported that Mr. Henry Phipps has given $20,000 to the Johns Hopkins Hospital for the purpose of establishing a separate out-patient department for persons suffering with tuberculosis.

GERMS IN BOOKS. — It is reported that the municipal authorities of Berlin are about to undertake to exterminate microbes in the books of public libraries. This possible source of the spread of infection has long been recognized and, we believe, in certain cases demonstrated. The attempt is to be made to disinfect all books after use, by means of a municipal disinfection station.

THE ALBANY MEDICAL ANNALS. — The current number of the *Albany Medical Annals* celebrates the beginning of the twenty-fifth year of this excellent periodical. A sketch of the history of the journal, founded in 1880, is given by Drs. F. C. Curtis and W. G. Tucker, in which the growth from small beginnings of a periodical, which is now representative of the medical work of its city, is briefly portrayed. The volume contains 208 pages with a number of excellent articles. We congratulate the journal on this, the beginning of its twenty-fifth volume.

PROGRESS NUMBER OF THE INTERSTATE MEDICAL JOURNAL. — The *Interstate Medical Journal* of St. Louis published in its January number, as has been its recent custom, an epitome of the important medical literature of 1903, included under twelve headings. As a summary of the best work done during the preceding year it should be of service to those whose time is too limited to consult the original sources, and these are certainly many.

BULLETIN OF THE AYER CLINICAL LABORATORY. — The Ayer Clinical Laboratory of the Pennsylvania Hospital has issued the first number of a bulletin, the publication of which is provided for by a fund given by Mr. F. F. Ayer. The bulletin will appear whenever sufficient material accumulates from the work done in the laboratory. The principal paper in the present issue is an elaborate article by Dr. Longcope on "The Pathological Histology of Hodgkin's Disease."

THE DEATH OF FRIEDRICK JOLLY. — The death of Professor Friedrick Jolly is announced. He was born at Heidelberg in 1844, later held chairs at Würzburg and at Strasburg, and on the death of Prof. Westphal was called to the important position of Professor of Psychiatry and Neurology in Berlin, a position which he held up to the time of his death. Professor Jolly contributed widely to medical literature in his special branch, but was never so prolific a writer as certain of his colleagues.

CENTENARIANS. — The following persons are said to have lived beyond the one hundred year mark:

Mrs. Sallie R. Higgs died in Owensboro, Ky., at the reputed age of one hundred and nine years. She was married at seventeen, had twelve children, the youngest of whom is now seventy-one years old.

Mrs. Catherine K. Steele of Lyndeboro, N. H., died Jan. 24, at the age of one hundred and two years. Beyond a slight deafness she was without physical infirmities at the time of her death.

Mr. Caleb Thorpe, supposed to have been the oldest living veteran of the Civil War, has recently died at the age of one hundred and three in Millersburg, Ohio. He leaves a widow who is reputed to be one hundred and one years old.

BOSTON AND NEW ENGLAND.

A PRINTERS' STRIKE. — Owing to a strike among the printers the publication of the JOURNAL this week has been unavoidably delayed. We ask the consideration of our readers for this delay and also for any typographical errors that may occur.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Feb. 3, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 47, scarlatina 32, typhoid fever 2, measles 151, smallpox 0.

Salt on Sidewalks and Streets. — The extreme rigor of this winter's weather has induced the Boston Board of Health to relax somewhat the enforcement of its regulations against the free use of salt on sidewalks and streets. But the practice has been resumed with such recklessness, that the board has been forced to remind citizens and corporations of the existence of the ordinance and of the deleterious effects on health of the well-known slushy freezing mixture.

Ingersoll Lecture for 1904. — It will be of interest to the medical profession to learn that this year the Ingersoll Lecture of Harvard University will be delivered by Dr. William Osler of the Johns Hopkins Medical School. This lectureship was established in 1893 with the proviso that each lecture should deal with some aspect of the general subject of the "Immortality of Man." Previous lectures have been given by Professor James, Professor Royce and the late Mr. John Fiske. The question has not hitherto been discussed from the physician's standpoint, and will, no doubt, excite particular interest on this account. The announced subject is "Science and Immortality."

Bequest to the Lowell General Hospital. — Mr. Frederick Ayer has given $50,000 to be used exclusively for the construction of a building in connection with the Lowell General Hospital. The first floor is to be devoted to women and the second to men, with accommodations on each floor for from twelve to fifteen patients. A maternity department will be connected with the building.

The Boston City Hospital Alumni Association. — The Alumni Association of the Boston City Hospital will hold its annual meeting at Young's Hotel on the evening of Wednesday, Feb. 10, at 6 o'clock. Dinner will be served at 6.30 o'clock, immediately after the business meeting. Dr. Charles P. Bancroft will preside. The hospital will be open to the members during the day. Ward visits, medical and surgical, and operations in the amphitheater (10 to 12.30) will be followed by luncheon in the hospital library.

NEW YORK.

Medical Society, State of New York. — On Jan. 28 Dr. Hamilton D. Wey of Elmira was elected President of the Medical Society of the State of New York and Dr. Joseph D. Bryant of New York, Vice-President. Drs. F. C. Curtis and O. D. Ball of Albany were re-elected as Secretary and Treasurer respectively.

Superintendent of Hospital in Korea. — Dr. Edward de Mott Stryker of Raritan, N. J., has started for Tabowie, Korea, to take charge, for three years, of a hospital which has just been established there by the Oriental Consolidated Mining Company.

Diphtheria Antitoxin for Chicago. — The Health Department has recently made a shipment of diphtheria antitoxin to Chicago, in response to a request from Dr. Reynolds, Commissioner of Health there, who stated that on Jan. 15, when bids were received for the ensuing year, the three manufacturing firms bidding for the furnishing of the supply doubled their prices. Health Commissioner Darlington has announced that if it is necessary in the interest of the poor, the output of the department's laboratories will be doubled, trebled or quadrupled, so that all the cities in the country may secure antitoxin at a reasonable rate.

A Delayed Verdict. — On Jan. 28 the Court of Appeals at Albany affirmed a verdict of $4,500 damages against the Delaware, Lackawanna & Western Railroad company in favor of Ellis R. Williams, who while serving as a brakeman in the employ of the company was injured on July 8, 1882. In the meantime the case has been tried no less than six times. It is believed that the loss to the company, including costs, will amount to $7,000.

Miscellany.

AMERICAN NEUROLOGY OF TODAY.

We print the following from the response to this toast by Dr. G. L. Walton, at the celebration of the Twentieth Anniversary of the Philadelphia Neurological Society, Jan. 27, 1904.

Twenty years ago, from each of the principal cities, a pitiful little group of sad-faced scientists gathered yearly in New York, to find mutual encouragement in pursuing a specialty which gave them at home the reputation of being rather persistent cranks who lacked the aptitude to deliver a child or amputate a limb, and who had the curious taste to prefer the study of physiology to the practice of medicine.

Neurological practice consisted largely in pushing the plodding pole and the painful Pacquelin up and down the backs of such chronic cases as were referred by other practitioners, who had exhausted their own therapeutic imaginations. The remainder of the neurologist's time was largely occupied by listening to the tale of the hypochondriacal and the ideo-obsessive psychopath, who goes from office to

office with preconceived and unshakable diagnosis of his own case, in the defence of which he exhibits enough argumentative skill, and prepares sufficiently voluminous briefs, to make a fortune in court, but who is generally unable, or if able, unwilling, to pay for the unsuccessful ministrations of his long retinue of medical advisers.

The professor of clinical medicine taught a few nervous diseases of fairly well-known pathology and a few with an imaginary pathology, like that peculiar form of myelitis whose foundations were laid in emotional excitement and whose development was induced by sleeping on the damp ground, bodily over exertion, and sexual excess. [1] Where there was a chair of neurology, its occupant was allowed to exercise his vagaries for the amusement of such exceptionally inquisitive students as possessed a childlike desire to know what was on the inside of the skull and vertebral column, those legitimate boundaries of anatomical research whose contents were made known to the general student by anatomical plates, from which he could learn little more of the spinal cord compared to what he is taught to-day, than he could from cross sections of a Pittsburg stogy.

Nor were extensive opportunities for anatomical and pathological study of the nervous system offered at that time even by those who pursued this branch, either in this country or abroad. The only opportunity I found in Leipzig in 1881 for neuro-pathological study was the privilege of setting up my microscope alongside that of Strümpell in Cohnheim's Laboratory, helping myself to pieces of his spinal cords, and extracting such information from him as my modesty allowed me to request. This was, in fact, a golden opportunity, to which, I fear, I did not half do justice, but except for that fortunate chance I should have been completely at a loss.

American as well as foreign neurology of to-day offers marked contrast with this picture. Neurology is now generally accorded a dignified and respected place, not only in the curriculum of the school, but by the medical practitioner. The neurologist is not only regularly consulted by the surgeon regarding the advisability of operation on brain, cord or peripheral nerve, and by the physician on obscure neurological cases, but his opinion is given weight by both surgeons and physicians and by other specialists in those obscure disorders, whether of nutrition, of motion, or otherwise involving organs outside the nervous system which baffle diagnostic skill.

The pathological work has advanced meantime with equal or greater rapidity. The second-year students in the Harvard Medical School now spend every day for a month examining pathological and healthy specimens of cord and brain, both macroscopically and microscopically, and by the time they take the fourth-year elective they are able to keep some of us guessing, and in their turn instruct the instructor.

The pathological material the student sought in vain twenty years ago, even on the Continent, he may find to-day in the laboratories of the various general hospitals, and in even greater profusion, and more extensively studied, in the hospitals for mental disease. An example of this advance was given only a month ago in this city, in the remarkable demonstration of neurofibrils, prepared in the Shepard and Enoch Pratt Hospital at Baltimore.

From the numerous instances of neurological advance in pathological diagnosis, I need only mention the monograph of Roberts on "Wasting Palsy," published in 1858, in which he describes amyotrophic lateral sclerosis, and states that the cord in this disease shows no characteristic changes either macroscopically or microscopically. As an instance of therapeutic progress let me remind you that even twenty years ago the surgery of the nervous system was in its infancy.

The present status of the pathological diagnosis of nervous diseases offers marked contrast to that of the comparatively recent date cited, when spinal diseases were classified only by their symptoms

Drug therapy in neurology, in spite of various experiments, is much the same as twenty years ago, except for certain modest but useful acquisitions, like the coal tar products and the thyroid extract; but the armamentarium of the neurologist has been materially increased of late by the development of a system of rational hydrotherapy and other forms of physical therapeutics.

Cerebral and spinal surgery, thanks largely to the neurologist, has now reached so high a scientific plane that its limitations are due to the serious nature of the diseases themselves, not to lack of knowledge on the part of the neurologist or technical skill on that of the surgeon.

While his fellow practitioners are awakening to the importance of the work of the neurologist, he, in his turn, is becoming more and more keenly alive to the importance of keeping, as far as possible, in touch, not only with allied branches, such as psychiatry and comparative neurology, but also with the deductions to be drawn from blood examination and blood pressure, cytodiagnosis and the relation borne by the ductless glands to psychic and somatic life, to say nothing of modern bacteriological methods and the recent investigations in physical chemistry, which seem almost on the verge of initiating us into the mysteries of the nervous impulse itself, and the meaning of myelinization.

I thank you, Mr. President and gentlemen, for the honor of addressing you and for the great pleasure of meeting you to-night. I bear the greeting of my colleagues, members of the Boston Society for Psychiatry and Neurology, who join me in wishing we were sufficiently near to allow more frequent interchange of courtesies. The Philadelphia Neurological Society has occupied, for the past twenty years, the forefront of every advance, and I can wish it no greater felicity than the maintainance of its well-earned prestige.

Correspondence.

LETTER FROM UPPER EGYPT.

CLIMATE. GROWTH OF ASSOUAN. RESURRECTION OF PHILAE. GOLF. ERADICATION OF OPHTHALMIA. A BISHARIN MOTHER. "PIGEON" ARABIC. SIR STEPHEN MACKENZIE, M.D.

ASSOUAN, UPPER EGYPT,
Jan. 10, 1904.

MR. EDITOR: The brief but acceptable apology for winter which one usually receives in this part of Egypt has not yet been offered. On the contrary, the weather thus far has been of the sort to be expected in March — the thermometer registering 90° F. on several occasions during the past three weeks. In Cairo it is cool and heavy rains have already fallen in Lower Egypt, which leads such of us as have been wise enough to come up the Nile in good season to congratulate ourselves on our foresight.

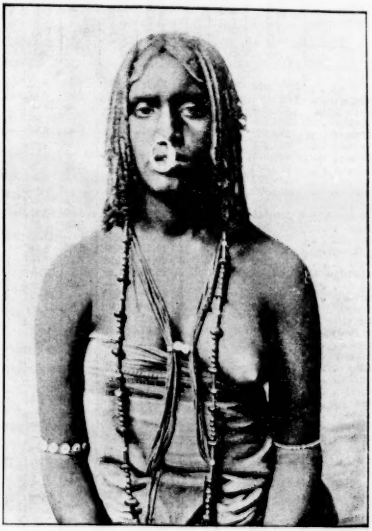
The season promises to be a most successful one, and very soon the hotel accommodations of the country will be strained to shelter the crowds which the absence of cholera and plague scares and the cold summer which prevailed throughout the world will attract to Egypt. Assouan is being constantly improved in many ways: roads are being widened and well ballasted, pretty little public gardens are springing up along the river front, and new and substantial buildings are being erected.

The gates of the Great Barrage have been recently opened, and Philæ has risen from the Nile not a bit the worse for its long submersion. Those who prophesied that the lines of its temples would be injured by adhesion of river mud are agreeably disappointed, for the little island was never more beautiful. Every day parties visit it to make sure of seeing this gem of all Egypt before the water is again held back and the Nile hides most of its beauties.

Golf has at last come to Assouan, and a very "sandy" nine-hole links has been made. A clubhouse of mud brick is being quickly built, and in a few days coming "events" will cast their shadows on the hotel bulletin boards.

A most interesting experiment is now being carried out. Sir Herman Casell donated £10,000 last spring for the purpose of eradicating, if possible, the dreadful scourge of Egyptian ophthalmia, which causes partial or complete loss of eyesight in so many cases.

It is certain that the flies, which are permitted to remain on and about the babies' eyes, are a potent cause of the disease, which is most difficult to cure unless in the early stages. Three reasons are given for this stupid neglect on the part of Egyptian mothers: laziness; the belief that Allah sends the flies and ill luck must follow their dispersion; and, lastly, that they take away the poison — the fact that they also bring it being completely ignored.



That the women are lazy and superstitious is undoubtedly true; but they are fond of their children, and I fancy the last-named reason is the true one.

Be that as it may the sanitary department has sent out well-qualified medical men with a complete outfit of camels, tents, medicines and supplies of all sorts to begin the crusade, by moving about the country and demonstrating to the natives that the disease is curable, and at the same time preaching the doctrine of cleanliness plus the vigorous use of a fly switch.

If this sanitary caravan is within fairly easy reach (it is in the Fayoum at present writing) when I go down the river, I hope to visit it and learn at first hand what progress is being made.

Here, where flies are comparatively few, one rarely sees ophthalmia, and I have never happened to observe a case in the Bisharin camp, just outside the town.

The average nomad Arab is healthier, cleaner, braver and in every way a better man than the dwellers in towns and mud villages, and when water is scarce these sons of the desert "wash" in fine sand!

A BISHARIN MOTHER.

Those of us who are beginning to qualify as "old Egyptians" gradually acquire a certain knowledge of what may be termed "pigeon" Arabic. The climate is not such as conduces to committing to memory what good linguists lightly refer to as "the few simple rules" (which a bountiful crop of exceptions serve to prove) that aid so much in acquiring the language; and we content ourselves with the ability to make known our simplest wants. The pronunciation is comparatively easy, the crux being the *kh* at the beginning of a word. This has the sound of *ch* in loch, as the Scotch pronounce it, and comes off very well with what I believe is known as a "flying start;" but unless it happens to be terminal is practically impossible for the average (foreign) tongue.

Some of the minor amenities of ordinary intercourse gradually force themselves upon us, as, for example, the addition of "O thou blessed one" to the ordinary form of salutation. This is invariably received with a pleasant smile by the person addressed and also produces a mild sense of triumph in the speaker.

The sounds of the language as spoken by adults is harsh and strident, and to listen to the conversation of two housewives from the roofs of their respective mud huts is a torture to sensitive ears.

Among the old Egyptians who frequent Assouan is Sir Stephen Mackenzie, M.D., who is subject to asthma if he remains in England during the winter months, but is quite free from it in this clear dry air. As I sit writing by an open window with the thermometer standing at 73° F. in the room, it seems hardly possible that I have made no error in my date.

F. G. M.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JAN. 23, 1904.

CITIES.	Population Estimated, 1904.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported, 3,042; under five years of age, 772; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 593, acute lung diseases 790, consumption 410, scarlet fever 42, whooping cough 4, cerebrospinal meningitis 9, smallpox 2, erysipelas 14, puerperal fever 12, measles 27, typhoid fever 33, diarrheal diseases 78, diphtheria and croup 61.

From whooping cough, New York 2, Pittsburg 1, Quincy 1. From smallpox, New York 1, Pittsburg 1. From cerebrospinal meningitis, New York 7, Somerville 1, Adams 1. From erysipelas, New York 5, Chicago 2, Baltimore 1, Pittsburg 1, Providence 1, Boston 2, Worcester 1, Quincy 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,425, for the week ending Jan. 9, the death-rate was 20.4. Deaths reported, 5,968; acute diseases of the respiratory organs (London) 248, whooping cough 121, diphtheria 60, measles 132, smallpox 5, scarlet fever 36.

The death-rate ranged from 7.9 in Barrow-in-Furnace to 41.7 in Preston; London 19.4, West Ham 16.3, Brighton 25.6, Southampton 15.3, Plymouth 15.1, Bristol 17.6, Birmingham 23.4, Leicester 17.4, Nottingham 23.1, Liverpool 26.7, Bolton 20.2, Manchester 24.6, Salford 24.1, Bradford 21.2, Leeds 22.6, Hull 17.5, Cardiff 17.7, Rhondda 21.3, Marthyr Tydfil 40.1, Kings Norton 16.4, York 19.9.

METEOROLOGICAL RECORD.

For the week ending Jan. 23, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

RECENT DEATHS.

DANIEL FRANCIS MURPHY, M.D., M.M.S.S., died in Woburn, Jan. 31, 1904, aged fourty-four years.

GEORGE CLINTON HALE, M.D., son of the late Dr. Charles Hale, of Greenbush, N. Y., and a great-grandson of Governor George Clinton, died at Catskill, N. Y., on Jan. 30, in the seventy-second year of his age.

GEORGE H. R. BENNET, M.D., of Brooklyn, N. Y., died on Jan. 26, at the age of sixty-seven years. He was graduated from the medical department of the University of the City of New York in 1860, and during the Civil War was a surgeon in the Twenty-Third New York Regiment.

ROBERT M. WEED, M.D., of New Rochelle, Westchester County, N. Y., died on Jan. 25, at the age of forty-nine years.

PHARMACOLOGIST.

BUREAU OF PLANT INDUSTRY, DEPARTMENT OF AGRICULTURE.

The United States Civil Service Commission announces an examination on March 1, 1904, to secure eligibles from which to make certification to fill a vacancy in the position of pharmacologist (male) in the Bureau of Plant Industry, Department of Agriculture, at $1,800 per annum, and other similar vacancies as they may occur.

The person appointed to this position must be a man trained and equipped with the knowledge and experience necessary for isolating and handling poisonous and other active principles of plant origin. He must be trained in animal physiology and pharmacology, and must have had experience in studying by exact laboratory methods the effect exerted on the different animal functions by the active principles of plant origin. He should be familiar with the best forms of apparatus used in carrying on such experiments and should have abundant laboratory experience in making such investigations. He should be able to read at least French and German, in addition to English. Age limit, twenty years or over.

This examination is open to all citizens of the United States who comply with the requirements.

Persons who desire to compete should at once apply to the United States Civil Service Commission, Washington, D. C., for application Form 1312, which should be properly executed and filed with the Commission at Washington, with the material required, prior to the hour of closing business on March 1, 1904. In applying for this examination the exact title as given at the head of this announcement should be used in the application.

Issued Jan. 29, 1904.

REMARKS UPON CHOLECYSTECTOMY AND CHOLECYSTOSTOMY, WITH SPECIAL REFERENCE TO THEIR COMPARATIVE SAFETY AND EFFICIENCY IN THE TREATMENT OF BILIARY AFFECTIONS.

BY MAURICE H. RICHARDSON, M.D., BOSTON,

Professor of Clinical Surgery, Harvard University.

THE questions when to drain the gall bladder and when to remove it are, in the present state of our knowledge, very difficult ones to decide. In my operations upon the biliary passages during the present year I have extirpated the gall bladder more frequently than I did formerly. The indications for complete removal have seemed more numerous and less questionable. In certain instances I have removed a gall bladder that was not more seriously diseased than many have been in previous permanently successful cholecystostomies. I am inclined to believe that in operations which do not permit easy and prolonged drainage the chief benefit of surgical intervention in gallstones is lost. I must admit that I am more and more convinced, by these cases in which there has been no free and prolonged drainage, that my earlier views were the proper ones, and that in the performance of cholecystectomy without providing for such drainage we are not only losing one of the most beneficent results of the operation, but are occasionally subjecting a patient to grave risks.

The dangers of cholecystectomy and cholecystostomy in simple cases are probably slight. An incomplete review of my private gall-bladder operations in 1902 and 1903 shows in a total of 51 operations, four deaths; two in 1902, and two in 1903. None of these deaths could have been prevented. In 1902 one patient died of pneumonia in advanced cholecystitis, for which drainage was made. The patient was *in extremis*. A second died of pulmonary embolism, during a satisfactory convalescence from cholecystostomy for acute cholecystitis. In 1903 one patient died of shock within forty-eight hours after cholecystostomy and choledochotomy. The second died of subphrenic abscess after removal of the gauze drain, though the convalescence during the first two weeks was very satisfactory and encouraging.

The arguments based upon mortality in such cases as these have little weight. The method of operation made probably little difference. The patients would have succumbed just the same after any operation of magnitude, or, indeed, after any operation.

The reason why during the past year I have resorted more frequntly to total extirpation is hard to tell. I have been influenced somewhat by the advocacy of others whose experience and opinions I respect; and I have thought perhaps that by my adherence to older ideas I was neglecting opportunities for better immediate and permanent results. A second influence has been the great anatomical attractions of extirpation; and a third, the repugnance I feel against any operation which fixes to the anterior abdominal wall by a local area of adhesions a freely movable organ. Furthermore, I have hoped by extirpation to avoid the great tendency to ventral hernia seen in drained wounds of the right upper quadrant. Another important element has been found in those changes in the gall bladder which at the time of operation made drainage difficult and unsatisfactory. Finally, I have been influenced by changes in the gall bladder itself which, though permitting satisfactory temporary drainage, seemed unlikely to be relieved permanently by that drainage.

The number of cases personally observed and treated, upon which my views are chiefly based, includes 200 operations upon the biliary passages — 140 private and 60 hospital. This list is incomplete, however, as some cases have been overlooked. The number not operated upon will comprise many more cases; and the number which I have observed in the wards of my colleagues will add several hundred more. My views are chiefly influenced, however, by my own cases, for it is these only with which I have been brought into close personal contact.

The operation of cholecystectomy is, in my experience, a very satisfactory one. The mortality has been small; convalescence has been rapid, and, with a few exceptions, permanent; and there is little tendency to hernia. Unfortunately, the data as to the permanent effect of total extirpation — either upon the general well-being of the biliary passages or upon the liability to the re-formation of gallstones — are insufficient for the formation of a positive opinion; for what are one, two, or five hundred cases of a lesion which permits combinations and complications of an almost infinite variety?

The analogy between the gall bladder and the appendix would seem in some respects a close one, and yet the resemblance is more apparent than real. The appendix is, compared with the gall bladder, simplicity itself, and it is impossible to draw deductions from the much greater experience that we have had in the one to aid in the solution of questions in the other.

In the case of the appendix there is simplicity in anatomical structure, in anatomical relations, in modes of infection, in the progress of the lesion and in the ultimate anatomical changes.

The anatomy of the biliary passages, on the other hand, is complex; the ramifications of the bile ducts are far-reaching; the anatomical relations are of the first magnitude. Moreover, the functions of the gall bladder are not understood. That it acts as a reservoir for storing bile is the most obvious idea, and yet this function cannot be of any considerable importance. I have seen many cases in which there has not been the least interference with digestion or with nutrition after the removal

of a gall bladder. In many other patients whose gall bladders have been for years apparently useless I have failed to observe any symptoms attributable to that cause. There is no analogy between the gall bladder and the appendix in this respect at least, except that both for all practical purposes may be regarded as useless appendages. I should not therefore consider the retention of the gall bladder as especially important were it deemed advisable for good reasons to remove it.

Though it is generally admitted that gallstones are the remote results of biliary infections; yet, from the great extent of the radicles of the hepatic duct, it is, in many cases at least, impossible to say where those infections first call into being the microscopic stone. Though the nidus of gallstones is usually in the gall bladder, in a very considerable number of cases the stones are said to form in the liver. Clinically I have found it impossible to tell in any case whether gallstones removed at a second operation were re-formed in the gall bladder or not. In one of my earliest cases, for example, I could feel a stone in the hepatic duct. In trying to dislodge and deliver this stone it slipped from my fingers and became lost in the depths of the great fissure, where I could not again detect it. I have removed large numbers of stones from the hepatic and common ducts, only to have 150 or more subsequently discharged from the hepatic duct through the tube into the dressings. Post-mortem examinations have for years shown the existence of gallstones in the liver. I have removed, in the course of gall-bladder operations, large numbers of stones from the hepatic duct, as well as from the gall bladder and from the cystic and the common ducts. I am convinced that in certain cases of so-called recurrence of gallstones, when I have had to operate a second time, that the stone or stones were in existence at the time of the original operation, and that they were either overlooked in the main ducts themselves, or that they lay hidden far beyond reach in the primary divisions of the duct in the liver. It must therefore be admitted that in a certain percentage of cases removal of the gall bladder itself with the cystic duct does not remove the already existing stones. It must be admitted also that, even if all the stones then existing are removed by cholecystectomy, stones may form anew somewhere in the remaining biliary passages.

I am fully convinced, however, that the gall bladder is the place where, in most cases, the gallstones form, and that their appearance elsewhere is either subesquent to their formation in the gall bladder or directly dependent upon anatomical and pathological changes induced in the hepatic radicles by gallstones which have passd out of the cystic duct. For all practical considerations this explanation seems to me perfectly reasonable and satisfactory. Even when I have removed a hundred or more directly from the hepatic duct, I have been sure that these hepatic stones were formed either in the gall bladder or in ducts dilated above an impaction. I have never seen clinically a gallstone in the hepatic or in the common duct without some evidence of its previous existence in the gall bladder itself. I do not believe that at the autopsy table a perfectly healthy gall bladder will often be found when gallstones have been demonstrated in the hepatic radicles. I would admit the possibility of gallstones in the liver, but would not consider this possibility as an argument of any appreciable weight in deciding between cholecystostomy and cholecystectomy.

I have removed in several cases a gallstone from the cystic duct, or from the hepatic or common, at a second operation. These stones have been of great age, and were undoubtedly overlooked at the time of the first operation.

One of the first facts impressed upon the operator in gall-bladder surgery is the great diversity in the pathological conditions existing at the time of operation. Although in the future it is not likely that ancient gall-bladder lesions will be as common as they have been in the last ten years, yet there will probably be a certain number of cases in which this lesion will be found well advanced, even if the patients are operated upon at the time of the earliest observed symptoms.

The scope of this communication does not include a discussion of the wide diversity in pathology. I have been impressed by these extraordinary variations from the normal at the operating table at a time when the interpretation of the pathological facts was of the greatest importance, and essential to the proper completion of the operation. It is enough to emphasize the fact that changes of great importance and of far-reaching effects, influencing not only the indications for operation but the methods of performing that operation, may be encountered in some of the apparently simple cases. The question of drainage or of extirpation may be settled at once by the condition in which the gall bladder will be found, and in which the operator will have no choice. The very first history of gallstones elicited from a patient by careful questioning may be that of the impaction in one of the ducts of a stone of great age, expelled perhaps after many years of chronic inflammation of the gall bladder, with ulcerations and contractions. Again, a gallstone may have formed and ulcerated through the gall bladder and into the intestine, and it may have caused a complete intestinal obstruction, without having given rise to any symptoms whatsoever. Nothing but the remains of the gall bladder may be found, contracted upon a dilated common duct — the whole taking place so gradually and so quietly as never to cause even a temporary discomfort. On the other hand, gall bladders may be, and often are, filled with large numbers of small gallstones; or the whole capacity of the gall bladder may be taken up by a single large stone, without any marked changes in the gall bladder itself and without any history

of pain or discomfort. Again, a single stone may cause symptoms of almost every kind as to severity and duration without either having become impacted in the cystic duct, or having caused ulceration of the mucous membrane, or having set up a gall-bladder infection. Furthermore, without any apparent cause, either from gallstones or from any other source, the gall bladder may suddenly become the seat of a fulminating infection and of an actual gangrene. And, finally, the gall bladder may become ruptured without any previous symptoms whatever. All of these lesions I have myself seen. Who can doubt that an experience of several thousand cases will show a diversity of lesions and of symptoms and of complications which is, as I have said, of almost infinite variety?

These are, however, but a few of the changes which I have observed in the course of perhaps some three or four hundred gall-bladder cases, including those operated upon and those not operated upon, as well as those discovered in the course of other abdominal operations.

Although an enormous amount of material is at hand to show the truth of the foregoing remarks, and to illustrate the tremendous diversity of pathological conditions, yet this field must be regarded — clinically, anatomically and pathologically — as a field which has been very incompletely explored. In a large number of cases the surgeon will find conditions present — before — during and after operations — for which he will search in vain for a precedent. Many questions in biliary surgery connected with the history — the physical examination, the indications for operation, the operation itself and the after treatment — are still unsettled. We do not even know what the early symptoms of gallstones are. We are seldom able to find any physical signs whatsoever, and we are sometimes unable to detect gallstones in the biliary passages, even with the hand inside the abdomen. Indeed, with the gall bladder between my fingers, I have been unable sometimes to detect gallstones before relieving distention; and yet I have found as many as a hundred stones after the relief of that distention.

The foregoing remarks may be regarded in the light of an introduction to the discussion of the chief subject of the evening — the comparative merits of cholecystectomy and cholecystostomy when a choice between these methods is possible. In many cases, as I have already said, there can be no choice. The gall bladder is already practically extirpated, and in many its condition is such that it must be extirpated. Choice is possible between the two methods only when the gall bladder is comparatively normal.

The question of function is perhaps the most important one from the standpoint of the physiologist. Whatever the truth may be as to the office of the gall bladder in nature, it has been demonstrated often enough that it is not indispensable. If not indispensable, the functions of the gall bladder have little importance in comparison with the advantages of draining the biliary passages. Should drainage be proved, as a rule, unnecessary or even dangerous, the gall bladder may be sacrificed without a thought as to its functions. On the other hand, if drainage is the best policy in gall-bladder surgery, and if the gall bladder provides the best route; if its retention causes, on the whole, less subsequent trouble than its extirpation, then the functions of the gall badder, whatever their importance, may be considered.

The practical arguments in deciding between extirpating and draining the gall bladder are three — perhaps four — in number, and are based : (1) Upon the comparative dangers of the two methods; (2) upon the comparative efficacy of preventing the recurrence of gallstones; and (3) upon the advantages of temporary drainage of the biliary passages ; finally, upon the possible necessity and increased difficulty of draining those passages at some future time.

(1) The comparative dangers of cholecystectomy and cholecystostomy. — As a rule, in gall-bladder surgery, as in all other kinds of surgery, the deeper the dissection and the nearer to vital structures the greater the immediate and remote dangers of the operation. This rule certainly applies to the surgery of the biliary passages. When the manipulations of the operation are carried on at the surface of the body, practically outside of the abdominal wound, there is no hemorrhage; the dissection involves no important structures; and infection, if it is present, is in the superficial areas of the abdominal cavity; the dangers of peritoneal contamination are easily and effectively guarded against. Clinical experience shows that cholecystostomy is the safest of all operations upon the biliary passages.

From the small number of deaths in my series of two hundred cases no deductions can be drawn. It would be unfair to compare the mortality following a number of difficult cholecystectomies with the same number of simple cholecystostomies, and *vice versa*. Taking a small number of any operations and drawing from them conclusions as to mortality rates is extremely misleading. It is absurd to base any argument, for example, upon my own results in extirpation, for all the deaths have been dependent upon causes other than the operation of extirpation by itself. It would be as absurd to claim for choledochotomies, of which I have had a considerable number with a small mortality, as great safety as that of an easy operation like cholecystostomy. I shall assume for purposes of argument that extirpation of a normal gall bladder is in itself an operation almost but not quite as safe as cholecystostomy; that the comparative mortality is, however, practically the same under similar conditions. If there is any choice on the ground of immediate danger, it is in favor of simple drainage — cholecystostomy.

There are conditions, however, in which drainage is quite as dangerous as extirpation. That is when the gall bladder is deeply contracted, hard to find, adherent to surrounding viscera and infected. In such cases the chief danger is from the deep dissection, the hemorrhage and the infection; and it makes little difference whether or not the remains of the gall bladder be removed above the point where the tube is fastened.

In cholecystectomy, even under the most favorable circumstances, a considerable area of the under surface of the liver is left bare and oozing; the cystic artery must always be cut and tied; the dissection is in close relation with the portal vein, and sometimes with the inferior cava; there is always the danger of tying the cystic duct so as partially to obstruct the hepatic and common ducts; the gall bladder may at any time be ruptured, or suddenly cut into, and the field flooded with its contents; hemorrhages from the raw surface of the liver are sometimes controlled only with the greatest difficulty. Occasionally, as I observed many years ago, after apparently the most effective ligation of the cystic duct, a burst of bile takes place from the depths of the wound, whence it must be carried to the surface wholly by the capillary drainage of a gauze wick.

Yet, with all these dangers, removal of a comparatively normal gall bladder, in experienced hands, probably does not, as I have said, add very materially to the risk. The mortality after extirpation of thin, elastic, translucent, unchanged gall bladders, loosely connected with and easily separated from the liver, with an easily isolated and tied cystic duct — is very small. I have had no deaths in such cases, whether operated upon by cholecystostomy or cholecystectomy. Barring certain complications which I will mention later, this seems a most effective method of treating gallstones in the gall bladder. The recovery is always more rapid than after drainage; there is less liability to hernia. But are the ultimate results as good? I believe that they are not.

When the comparative dangers of draining and of extirpating a changed gall bladder are considered,— when we have a gall bladder that is thickened, adherent and infected,— the dangers of extirpating such a gall bladder seem to me greater than those of draining that gall bladder. The question then comes up whether extirpation of such a gall bladder is not followed by much better permanent results than drainage. Operation upon an adherent, thickened, friable, septic gall bladder, with presumably a thickened, ulcerated, strictured duct, with or without gallstones, is a formidable operation, and one of very considerable mortality. The surgeon finds in such cases an increased amount of hemorrhage and greater difficulty in checking it, with much greater difficulty in preventing extensive peritoneal infection. When the gall bladder is contracted and thickened, when its fundus is far removed from the abdominal wound by gradual contraction, then the difficulties of drainage may be much greater than the difficulties of extirpation. In draining such a gall bladder it is necessary, first, to isolate it from surrounding structures — a procedure often of great difficulty, and sometimes resulting in rupture of the gall bladder and extensive infection of the surrounding parts. It is always difficult to fix a tube in effectively, so that bile will not be poured out into the depths of the wound. Once having isolated such a gall bladder down to the cystic duct, ligation of that duct and removal is a simpler and safer procedure than drainage of it.

However desirable it may be to extirpate a contracted, thickened and friable gall bladder, in many cases it is essential under these circumstances to drain the biliary passages. If these passages are not drained through the contracted gall bladder and the cystic duct, then the surgeon must seek for the common or the hepatic duct, and make his drainage through them. The simple extirpation of such a gall bladder is probably a safer procedure than attempted drainage through it. Under the pathological conditions which exist, however, it is generally essential to provide temporary drainage, either by deep cholecystostomy or by drainage through the common or hepatic duct.

The comparative dangers, then, of cholecystectomy and cholecystostomy are chiefly in connection with the normal and the comparatively normal gall bladder.

(2) The prevention of gallstones.— The weight of this argument depends upon the etiology of gallstones. If they are always formed in the gall bladder and nowhere else, this argument is of the greatest possible weight in favor of cholecystectomy. I have already considered briefly this question in the introductory remarks. I am convinced that as a rule gallstones are formed in the gall bladder, and there alone. I have never seen a case which led me to suspect the re-formation of gallstones either in the gall bladder or in the liver. In not a few instances I have been obliged to operate a second time, and I have removed at the second operation one or more gallstones. These stones were not new stones, however. I have found gallstones in the hepatic duct, high up in the liver. In one instance 150 were discharged from the hepatic duct during convalescence. These stones were, I fully believe, formed in the dilated hepatic duct.

The argument of preventing gallstones by removing at once the *fons et origo mali* is, in my mind, a very strong one, and it weighs almost wholly in favor of cholecystectomy.

On the other hand, if gallstones are formed in any appreciable number of cases in the liver, cholecystectomy without drainage of the biliary passages is undesirable. Drainage after cholecystectomy by means of a tube in the hepatic duct will give drainage for the time being. Should a second operation become necessary, drainage will be extremely difficult.

I am fully convinced by my own experience, however, that gallstones are extremely seldom re-formed, even in the gall bladder. That they may re-form in the liver is a possibility so remote that it need hardly to be considered in discussing the comparative merits of cholecystostomy and cholecystectomy. The argument of liability to re-formation, therefore, favors cholecystectomy rather than cholecystostomy, but the weight of this argument is light.

(3) Drainage of the biliary passages is the one great benefit to be gained by the operation upon the biliary passages, whatever may be the lesion for which the operation is undertaken. I am very strongly of the opinion that the free escape of bile through the wound for two or three weeks does more good than anything else connected with the operation. Hence any method which does not provde this free temporary escape fails in the most important element for permanent success.

By cholecystostomy drainage may be provided in the quickest and safest way. When the gall bladder is normal or comparatively normal — though perhaps at this time drainage is least important — a tube fastened in the fundus of the gall bladder by means of a purse-string provides a safe and efficient means for the escape of bile, and for the thorough washing out of all elements of sepsis, of every possible nidus of renewed infection or of repeated gallstone formation. Furthermore, in some way not easy always to understand, it provides for those symptoms and lesions originating in the pancreas. It gives the patient the very best chance for immediate and for remote recovery.

It is true that drainage of the biliary passages may be affected after extirpation of the gall bladder, by means of the cystic, common or hepatic ducts. This operation, however, is not so easy or so safe as it is by some regarded. To hunt for the hepatic duct after isolation of the gall bladder and cystic duct is no small operation in itself. I find it often difficult to demonstrate the hepatic duct in my regional surgery course. The cystic duct is sometimes so small that it will not admit any but the smallest probe. Moreover, the valves of the duct prevent the introduction of the probe. The hepatic duct, unless it is dilated by long-continued obstruction below it, is too small for the introduction of any but the smallest tubes. I need hardly add that the search for the hepatic duct in the depths of the wound requires a very long incision. The technical difficulties of hepatic drainage in the comparatively normal case are, I do not hesitate to say, of great magnitude, besides which such an operation as, say, the isolation of the cervical sympathetic from the jugular and carotid is a trivial task. I cannot imagine how hepatic drainage as a routine procedure can be seriously encouraged, either in connection with cholecystostomy or following cholecystectomy. Furthermore it will take a good deal to convince me of either the necessity or the wisdom of this course when there is at hand so safe and so efficacious a method as cholecystostomy.

Under certain conditions, however, drainage through the hepatic duct must be used whether cholecystostomy or cholecystectomy be performed. When drainage through the gall bladder has been ineffectual or unduly difficult, I have introduced a tube into the hepatic duct through the contracted gall bladder. In other cases, after extirpation of a contracted gall bladder, I have found no difficulty in so doing by incising the dilated duct. In a recent case I drained each primary division of the hepatic duct — one tube going into the right half of the liver, the other into the left. The gall bladder was a rough mass on the dilated common and hepatic ducts, which together resembled closely a thickened and somewhat contracted gall bladder. A free incision into this apparent gall bladder revealed two large openings, each admitting almost the finger tip. A tube in each provided the best kind of drainage. The comparative amount of bile from each half of the liver was then easily determined. The patient made a good recovery. In gallstone impactions of the common duct hepatic drainage is, of course, essential.

Cholecystectomy in the case of the normal or comparatively normal gall bladder does away with drainage, or should do so. If drainage is essential in gall-bladder surgery, cholecystectomy should never be performed in the comparatively normal gall bladder. When the gall bladder is abnormal — infected, contracted —it should be removed for reasons connected with its own pathological condition. Yet I have been surprised to find how many badly infected gall bladders have become perfectly healed after cholecystostomy. On the other hand, I have been disappointed to find fatal gangrene after draining an acutely infected gall bladder.

Drainage of the biliary passages in acute or chronic cholecystitis is indispensable. When, therefore, it is proposed to extirpate such a gall bladder, it is proposed to do away with drainage, except by methods difficult and dangerous already described.

My recent experience tends to confirm the objections to cholecystectomy expressed above. In three cases — all operated upon during the past three or four months — there have been very serious, not to say alarming, symptoms.

Mrs. A. L. M., aged fifty-three, a patient of Dr. Cochrane of Arlington, Vt., had suffered from biliary colic for twenty years. At the operation on June 26, 1903, I found a gall bladder everywhere adherent, contracted so close to the duodenum that separation seemed impossible. The fundus of this contracted gall bladder was at last delivered and tapped. The large, altered gall bladder was enucleated as well as possible. One hundred and seventy gallstones were removed, some of which were in the depths of the sacculated cystic duct. I sewed into the remains of the gall bladder and into the dilated cystic duct the largest drainage tube that I could get in. The whole appearance and feel of the region was that of malignancy, but there was no malignancy.

This patient was discharged from the hospital on Aug. 12. At that time there was a sinus giving exit to perhaps a pint of serum and about half an ounce of mucus in twenty-four hours.

The last of August Dr. Cochrane removed from the sinus two more stones: one as large as a large pea and the other about the size and shape of a kernel of buckwheat. For about a month after this patient's return home the sinus discharged a considerable amount of serum and mucus every day. At the end of this time there was a sudden discharge of bile. For four or five days there was a discharge of at least two quarts in twenty-four hours. The flow ceased almost as abruptly as it appeared. It reduced itself by half at each of the three consecutive dressings (twelve hours apart), and then the sinus closed entirely, and stayed closed.

The question of cholecystectomy and cholecystostomy in a case like this is one of very little importance. Practically the case may be regarded either as one of a very large opening into a very small gall bladder, or as one of a very large opening into the remains of a very small gall bladder. The element of extirpation has, I think, no bearing in a case of this kind. There was nothing else to do except what I did do. It has a bearing, however, on the subsequent history of the case. I have no doubt that the complications which followed the operation in this case were owing to the fact that the lesion, the manipulations of the operation and the drainage, all concerned the common, the hepatic and the cystic ducts — just as they do in extirpation of the gall bladder. The explanation of the symptoms would be either that the stone was overlooked, or that there was a temporary engorgement and swelling of the mucous membrane of the duct. This is one of the cases which is, as far as my experience goes, without precedent.

II. The second case was that of a man of fifty, a patient of Dr. Sullivan of Dover, N. H. The diagnosis was gallstones and chronic cholecystitis. On July 2, 1903, at St. Margaret's, I removed the gall bladder through an incision four inches in length at the outer border of the rectus. The gall bladder was adherent everywhere, and being very friable was removed with difficulty. The cystic duct was tied with silk, and a small gauze drain was left in the depths of the wound.

This patient was discharged from the hospital on July 25, well.

On Aug. 8 Dr. Sullivan wrote that he had been called to see Mr. L., who was suffering extremely from pain in the right side. He was vomiting yellow mucus, and he was jaundiced. The temperature was 101° and the pulse 100. After this attack there was tenderness in the region of the gall bladder, with recurring fever, persistent nausea and vomiting, with insomnia. There was gradual improvement in this case. The pain and soreness diminished; the patient had no further attacks of jaundice, and gained in health and strength, so that by the end of October he was able to resume his position as an engraver.

III. The third case was that of a patient of Dr. I. J. Clarke and Dr. C. E. Durant of Haverhill. The diagnosis made by Dr. Clarke and Dr. Durant was gallstones. I did not agree with this diagnosis, but advised exploration. The attending physicians were correct in their diagnosis. The gall bladder was distended with stones and with pus. It was everywhere adherent, its walls were rotten and friable, and it contained 90 gallstones. One very large friable stone was impacted in the cystic duct. In spite of every care in separating the adhesions of the gall bladder, it tore all to pieces. The fragments were all carefully removed, and the area was cleansed with salt solution and weak corrosive sublimate. An uncovered gauze wick was placed in the depths of the wound.

Two weeks after the operation the patient began to have severe pain, and she has been in pain ever since. She became jaundiced, and that jaundice has also persisted. At last accounts she was suffering severely, both from the pain and from the jaundice. On Dec. 24 I made a careful examination of this patient. There were no physical signs. On the chances, the symptoms are caused by the impaction of a stone which was overlooked at the time of the operation.

I see no escape from the conclusion that cholecystectomy without drainage is an incomplete and dangerous operation; and that cholecystectomy with drainage of the hepatic duct is an unnecessarily dangerous operation when cholecystostomy is so very easy and so safe.

The drainage of the hepatic duct, or the common, by means of a rubber tube has dangers, theoretically at least, which ought not to be disregarded. I refer to pressure ulceration upon the lining of the duct with subsequent cicatricial stenosis. The duct is elastic, contractile, with thin and presumably easily injured mucous lining. The area of mucous lining to spare is extremely limited. It is easily conceivable that two weeks' drainage may result in a serious permanent constriction of the duct. I have observed in dissections into the common duct, when that duct is dilated and thickened, that there may be a very considerable loss of substance as the result of that dissection. May not some of the cases of jaundice after operations upon the ducts result in this way from this cause?

Again, I cannot but regard free dissections and incisions in and about these delicate structures as attended by a hazard unjustifiable from changes — inflammatory, adhesive, or cicatricial — which can neither be prevented nor understood. In a word, there is a possibility of permanent damage even in the hands of the most experienced and skillful dissectors.

There seems to me no escape from the conclusion that biliary drainage through anything but the gall bladder is attended by grave risks of remote trouble — not to mention the greater hazard of the operation itself. Once convinced of the advantages of biliary drainage, one cannot escape the conviction that it is the height of folly to sacrifice in the very beginning of gallstone disease the means by which that drainage is easy and effectual. From this point of view cholecystectomy seems an operation of last rather than of first resort — an operation for old, contracted, infected, useless gall bladders,

through the remains of which, however, temporary drainage may be easily and safely established, as in my earliest operations published in THE BOSTON MEDICAL AND SURGICAL JOURNAL of April 28, 1892.

(4) The great difficulty of secondary operations upon the biliary passages, especially drainage after cholecystectomy, has been frequently impressed upon me when, after choledochotomy, or hepatic drainage with or without cholecystectomy, symptoms have seemed to demand renewed surgical measures. Considering the small number of operations which I have myself performed, the cases in which I have considered this question are few, and the cases in which I have actually operated still fewer. Natural efforts at cure have been almost invariably successful. All the cases that I have actually reopened have been those of permanent biliary fistula caused by a stone impacted either in the cystic or in the common duct. In one case a third operation was performed, the first being cholecystostomy, in 1894, for acute cholecystitis (colon bacillus); the second, in 1900, for stone in the cystic duct; and the third, in 1901, for stone in the common duct. The number of extirpations has been too small yet for any important or valuable deductions; but three out of the last seventeen have already raised this question. In two patients operated upon by competent surgeons I have been consulted for permanent fistula after extirpation of the gall bladder.

After all, the most important objection to extirpation of the gall bladder, when the cystic duct is ligated, is the loss of those great benefits which follow prolonged drainage of the biliary passages. It is true that drainage may be used in connection with cholecystectomy by putting a tube in the hepatic duct, but in many cases it would add enormously to the difficulty and danger of the operation. Moreover, it is a serious objection to extirpating the gall bladder that drainage in the future will be difficult.

The complications that have arisen after extirpations of the gall bladder in the last year, as in the cases previously mentioned, have been owing to interferences with drainage. I have not deemed it advisable in these cases to seek the hepatic or the common duct to establish drainage, hoping that the obstruction to the bile was owing to swelling of the mucous membrane, to a temporary infection, or to some condition which would of itself subside. In the first two cases the symptoms have, in fact, subsided, and the patients are now perfectly well.

Unless it shall appear that total obliteration of the gall bladder diminishes rather than increases these unpleasant post-operative complications, cholecystectomy must remain an operation of necessity rather than of choice. The greater beauty of the operation, the rapid convalescence, the firm scar, should count but little in comparison with the permanent safety and complete recovery of the patient, even at the expense of a long scar and a ventral hernia.

CHOLECYSTOSTOMY AND CHOLECYSTECTOMY. A STUDY OF A CERTAIN SERIES OF OPERATIONS.[1]

BY CHARLES L. SCUDDER, M.D., BOSTON,
Surgeon to the Massachusetts General Hospital.

IN the series of sixteen cases here recorded cholecystostomy was done seven times. The gall bladder in each case was attached to the abdominal parietes by suture to the peritoneum. Permanent drainage of the biliary passages was established and drainage of the quadrilateral space (Robson) beneath the gall bladder was provided for by a wick of gauze.

These cases recovered from the operation with one exception. The case which died was No. 4, a woman sixty-six years old, who developed a pneumonia before the gall-bladder fistula had closed and died some few days after the operation.

The general symptoms of these cases of cholecystostomy are here arranged in detail:

CASE I. Attacks of gall-bladder pain. No real colic; jaundice absent.

CASE II. Acute cholecystitis. Gallstones in the cystic duct; jaundice absent.

CASE III. Gallstones; colic; stones in the cystic duct; jaundice absent.

CASE IV. Gallstone attacks. Stones in the gall bladder; jaundice absent.

CASE V. Gallstone attacks. Stones in the gall bladder and the common duct; jaundice present.

CASE VI. Gallstone attacks. Gallstone in the bladder; tarry detritus in the cystic duct; jaundice absent.

CASE VII. Gallstone attacks. Stone in the common duct removed through the gall bladder; jaundice absent.

One case had pain referred to the gall bladder region, without genuine colicky attacks. One case was an acute cholecystitis, an acute infection in the presence of gallstones. Five cases had had genuine attacks of gallstone colic.

The contents of the biliary passages and gall bladder as found at the cholecystostomy are here stated in detail:

CASE I. Clear fluid in the abdomen, small in quantity; glairy, ropy mucus and a granular, pasty sediment in the gall bladder. No stones.

CASE II. A small amount of clear fluid in the abdomen; thick, cloudy mucus and inspissated biliary detritus in the gall bladder. Stones in the cystic duct. The culture from the contents of the gall bladder was sterile.

CASE III. Glairy mucus and a puriform-looking material, with a few stones in the gall bladder. The culture from the gall bladder showed bacilli coli communis.

CASE IV. Many stones in the gall bladder. The culture from the gall bladder showed bacilli coli communis.

[1] Read before the Franklin County Medical Society, Greenfield, Mass., Jan. 12, 1904.

CASE V. A stone in the gall bladder and one in the common duct.

CASE VI. One stone and a thick, tarry biliary detritus in the gall bladder. Culture from the gall bladder, bacilli coli communis.

CASE VII. A stone in the common duct. No stones in the gall bladder.

The stones were in the cystic duct in two cases, in the common duct in one case, in the gall bladder and common duct in one case, in the gall bladder alone in two cases. In one instance there was no stone but a pasty biliary sediment in the gall bladder and in the cystic duct.

Of these seven cholecystostomies one died of pneumonia. Five of the remaining cases have been carefully followed since operation. Only one case is absolutely well and without pain or discomfort referable to the gall-bladder region. In each of the other four cases there is more or less discomfort. The facts with regard to each of these are given in the detailed account.

Cholecystectomy was done in nine of these sixteen cases. The cystic duct was tied off and drainage provided from the stump of the cystic duct to the surface by means of a wick of gauze, which was removed after four or six days. All of these cases recovered from the operation.

The general diagnosis of these cases of cholecystectomy is here arranged in detail:

CASE VIII. Gallstone attacks without jaundice.

CASE IX. Gallstone attacks with temporary jaundice.

CASE X. Gallstone attacks with temporary jaundice.

CASE XI. Gallstone attacks; persistent jaundice.

CASE XII. Acute cholecystitis without jaundice.

CASE XIII. Gallstone attacks without jaundice.

CASE XIV. Biliary fistula.

CASE XV. Acute cholecystitis following cholecystostomy.

CASE XVI. Biliary fistula.

Five of these cases had rather characteristic gallstone colics. In one of these no gallstones were found, but a pasty biliary sediment filled the lower portion of the gall bladder and the cystic duct. Two were cases of acute cholecystitis. Two were cases of biliary fistula. One of these fistulæ was spontaneous; the other followed a cholecystostomy. The case of spontaneous biliary fistula had had two explorations of the gall bladder done previous to the cholecystectomy.

The contents of the biliary passages and gall bladder as found at operation are here stated in detail:

The contents of Case VIII: Cloudy fluid; gallstones; inspissated bile from the gall bladder.

CASE IX. Mucus; pasty, biliary sediment from gall bladder.

CASE X. Gallstones and no fluid.

CASE XI. Gallstones and no fluid.

CASE XII. Clear mucus, cloudy fluid, biliary slime.

CASE XIII. Slimy, granular biliary detritus and a gallstone in the cystic duct.

CASE XIV. Clear bile; no stones.

CASE XV. Clear mucus; no stones. The culture from the gall bladder: staphylococcus pyogenes aureus.

CASE XVI. Clear bile; no stones.

In only one instance was a culture taken and that was in Case XV. The culture showed the staphylococcus pyogenes aureus. This was a case of acute cholecystitis previously operated upon by cholecystostomy. The cholecystostomy wound had been closed some time. This patient convalesced without incident. In none of these cases were stones left unremoved from the common or hepatic ducts.

The end results of these nine cholecystectomies are particularly interesting. All the cases were traced and a report was obtained in each instance. The longest time which had elapsed since the operation was three years; the shortest time, one month. In each instance there has been no recurrence of gallstone colic and no discomfort whatsoever referable to the gall-bladder region. Each case considers herself well.

Of these sixteen cases, eleven showed no jaundice, or about 68%. Oehsner found in his cases that 50% had not had jaundice. One of the cholecystostomies had had jaundice, due to a stone in the common duct. Four of the cholecystectomies had had jaundice, three of which had temporary or fleeting jaundice, and one persistent jaundice.

Winslow has looked up the records of the cholecystectomies done at the Massachusetts General Hospital over a period of ten years. He will report the details of these cases at a subsequent date. A preliminary report made recently is instructive.

He finds that there have been forty-six cholecystectomies. Twenty-four of these cases have been traced and reports of their present condition secured. The results in twenty-two of the twenty-four cases have been perfectly satisfactory and might be termed ideal results. Two of the cases died subsequently,— one ten months after operation, the other two and a half years after the operation,— each with persistent symptoms, showing that they were not suitable cases for the operation of cholecystectomy.

Winslow has looked up the records, also, of the cholecystostomy cases done at the Massachusetts General Hospital during the past ten years. He finds that there have been 183 operations. Twenty-nine of these died within a week of the operation at the hospital, or 15%. Nine of these 29 deaths were malignant cases. Twenty-nine of the 183 cases, or about 18%, came to secondary operation, most of them because of biliary fistulæ following the cholecystostomy. Thirty-four cases of cholecystostomy, 13 of which were for malignant disease, have

been traced one year and more after the first operation and have been found to have had recurrent attacks or fistulæ persistent. Forty-six cases out of the 161 non-malignant cases gave good results, which might be called ideal results. That is about 28%. These were traced from one year to five years after operation.

It would seem, as some have thought, that the gall bladder and the biliary passages almost equal the appendix as sources of chronic disease and disability in adult life.

The general practitioner should be profoundly impressed by the pathological findings of the surgeon in operations upon the biliary passages and the gall bladder. This living pathology demonstrates that for months, and possibly for years, previous to operation, lesions have been in progress which have been unrecognized. It is possible that in a few of these instances diagnostic symptoms have been absent or concealed. It is far more probable that the attending physician has not recognized the signs of beginning trouble with these parts. It is a fact worthy of consideration that the patients whose cases are here recorded, as well as those mentioned by others in literature, complained of and suffered from what has been called gastritis, dyspepsia, chronic gastritis, indigestion, constipation, bilious headache, sick headache, sour stomach, biliousness, etc. Along with the ordinary symptoms associated with these troubles, enumerated above, occurred chills, loss of flesh, fleeting jaundice, sallowness, nausea, loss of strength, nervous prostration, anorexia, vomiting, pains not particularly localized, — perhaps extending from the general abdomen into the back, — general abdominal discomfort. During these months and years the physician has treated these sufferers expectantly, medically, palliatively, with pills and powders and liquid remedies, with indifferent success, as is now being made apparent by the brilliant success of surgical intervention in certain of these cases of lesions of the biliary passages.

The outspoken classical signs of cholelithiasis — namely, colic, jaundice and tumor in the gall-bladder region — may be absent. It is to-day not only possible but necessary for the physician to make a diagnosis of cholelithiasis and other lesions of the biliary passages, even if all these important classical signs are absent or in the background. It is true that many gall bladders are found at autopsy to contain gallstones, in cases not operated upon. It may be true, as is asserted, that most of these individuals complained during their lifetime of none of the classical symptoms of gallstones. Kehr's statement that only about 5% of those with gallstones in their gall bladders have symptoms seems to me to be rather misleading. Wherever there are gallstones there, there must at sometime have been an infection of a certain virulence. Gallstones represent the result of this infection. It is highly probable that many of the dyspeptic and gastric symptoms hitherto unsatisfactorily treated are symptomatic of beginning disturbances in the gall bladder and the biliary passages.

Adhesions about the gall bladder to the duodenum, to the small intestine, to the stomach, to the transverse colon, to the pancreas, and adhesions of the biliary ducts to the parts about, are known to cause great disability, with signs of gastric trouble. Upon the removal of these adhesions and their cause, when possible, the distressing symptoms vanish. This is the tale told now repeatedly of pathological conditions by gall-bladder patients.

The surgeon finds at operation three general groups of cases, definite pathological groups: the inflammatory disturbances, the cholecystitidies; the gallstone cases, cholelithiasis; and the cases of carcinoma (Quincke). Brewer has admirably arranged the diseases occurring under the above classification as follows: The inflammatory diseases, —

(1) Cholecystitis — subacute.
(2) Cholecystitis — acute (see Case II).
(3) Cholecystitis — chronic (empyema).
(4) Cholecystitis in contracted gall bladder (see Case X).
(5) Cholangitis.

All these diseases are associated more or less closely with signs of fever, local tenderness and pain. The latter disease, cholangitis, is usually, according to writers, associated with stones in the hepatic or common duct, or both, and may be characterized by sepsis of a marked type. Just what the term "cholangitis" means is not altogether apparent. It is used with one meaning by the clinician, be he physician or surgeon, and in an entirely different sense by the text-books of pathology. That the surgeon should use the term to express a clinical picture which, in the event of the death of the patient, does not present a definite pathological condition is not only unfortunate but inaccurate.

In cases of cholelithiasis the surgeon finds various combinations of conditions, arranged by Brewer in somewhat this fashion:

(1) Stones in the healthy gall bladder, ducts free.
(2) Stones in the healthy gall bladder, cystic duct temporarily obstructed by inflammatory swelling or slime (see Case VI).
(3) Stone or granular detritus impacted in the cystic duct (see Case III).
(4) Stone in the hepatic duct.
(5) Stone in the common duct, acute obstruction.
(6) Stone in the common duct, movable chronic obstruction (see Case V).
(7) Stone in the common duct, impacted, chronic.

The symptoms of importance in this group of cases will be those of pain, fever, vomiting and jaundice.

The carcinoma cases according to Brewer may be classified as follows: Tumor of —

(1) The gall bladder.
(2) The cystic duct.
(3) The hepatic or common duct.

(4) The neighboring viscera pressing upon the common bile duct.

The symptoms associated with this group of malignant diseases usually are signs of jaundice, tumor, ascites and cachexia.

It is important that one should have a definite conception of the pathological lesions which may exist in any individual case of disease of the gall bladder and biliary passages. Diagnosis will then be far more likely to be correct and treatment intelligent. It is necessary that a careful analysis of each symptom should be made in order to properly interpret its relative and absolute importance.

The surgeon having, during the past few years, made clear the living pathology of gallstone and biliary passage diseases, and having to these former medical cases brought some measure of relief, the question very naturally arises, What does the surgeon suggest for the treatment of these cases, especially of chronic gall-bladder and biliary passage trouble? There are two generally accepted procedures which the surgeon has found to be of value, namely, cholecystostomy and cholecystectomy. By cholecystostomy the gall bladder may be drained of its abnormal or normal contents, and if the cystic duct is patent, drainage at the same time may be established of the deep biliary ducts, and if the pancreatic duct opens advantageously it likewise may secure drainage through the outlet in the incised gall bladder.

The advantages of a cholecystostomy are that ordinarily it is a simple procedure, may be readily accomplished, and that the mortality is not great and the deep ducts are drained if they are patent. Obviously, in cases of cholangitis, so called, or chronic pancreatitis this procedure is of importance. I think there is, however, a mistaken impression on the part of most surgeons and medical men as to the end results of cholecystostomy. In general, cholecystostomy is supposed to afford satisfactory results. The group of cases here reported in detail, although small, confirms the returns which Winslow makes from a larger group of cases operated upon at the Massachusetts General Hospital, and the finding is that in cases of cholecystostomy persistent biliary fistulæ exist in a number of cases; that the deeper ducts are often not easily explored through the opened gall bladder and adherent parts, consequently stones are left in the deep ducts to be heard from later; that a dragging pain is present in many cases, due to the adhesions between the gall bladder and the abdominal wall, necessitated by the old technique of the cholecystostomy.

With regard to the procedure of cholecystectomy, there are certain cases in which the presence of dense adhesions about the gall bladder, cystic and common duct preclude the possibility, without subjecting the patient to a somewhat prolonged operation, of removal of the gall bladder. Obviously, in such cases cholecystectomy would be unwise. These cases, however, should be fewer and fewer as the surgeon becomes familiar with the anatomy of this region and with the technique necessary to overcome what seem at first insurmountable difficulties.

It is important before cholecystectomy is undertaken that the surgeon be sure that the deep ducts are patent and that there are no stones in the common and hepatic ducts. Should a cholecystectomy be done when stones exist in the deeper ducts these stones will certainly cause trouble, and the termination of such a case may be most unhappy. It seems to me that the exploration of the deeper ducts is rendered comparatively easy by the splitting of the gall bladder upon its under surface and of the cystic duct down to its termination. Coupled with this procedure the deep exploration is facilitated by the arching of the back as suggested by Robson, by means of a hard cushion placed under the lumbar spines, by upward lifting of the liver and traction downward upon the duodenum.

Cholecystectomy is certainly a wise procedure in cases of cholecystitis and its resulting acute conditions of gangrene and empyema of the gall bladder. These conditions are often entirely limited to the region of the gall bladder, the deeper ducts not being involved. In the absence of the involvement of the deep ducts the gall bladder should be treated as an isolated sac and removed.

Wherever gallstones exist in the gall bladder there may be a latent infection, ready to break out at any time; a re-infection may occur from the usual source, the duodenum: so that these two facts are to be given consideration in deciding whether or not the gall bladder should be removed.

It is a fact that carcinoma of the gall bladder is found in about 14% of the operated cases of gall-bladder trouble. In 15% of the secondary carcinomas of the gall bladder there are no gallstones found in the gall bladder itself. On the other hand, in 80% of cases of primary carcinoma of the gall bladder gallstones are present. It is a fair conclusion, therefore, to suppose that the presence of gallstones is an important etiological factor in the production of carcinoma, so that the leaving of the gall bladder as in a cholecystostomy affords the opportunity for the development of carcinoma.

There have been few instances of the formation of gallstones after a cholecystostomy; Homans reported one case, Kehr has reported two cases. It is more than likely that in many of the cases in which the formation of gallstones is said to have occurred after a cholecystostomy, the gallstones found at the second operation were already present in the gall bladder but unremoved at the time of the primary operation, so that the leaving of the gall bladder *in situ* does not involve a very strong probability of the formation of more gallstones.

The doing of a cholecystectomy does not preclude the possibility of drainage of the deeper parts, either by the procedure of Mayo, in dissecting out the mucous membrane of the gall bladder and leaving its peritoneal and fibrous

coat to serve as a trough from the deeper ducts to the surface, or the procedure of Kehr, of drainage of the deep ducts directly through a rubber tube.

The mortality of cholecystectomy is low. Kehr, in 100 cases, shows a mortality of 3%. In the small series here presented there was no mortality. The mortality following the hospital cases quoted by Winslow must be studied carefully before making it count against cholecystectomy. Examination of the group of deaths in Winslow's cases does not make the mortality tell against cholecystectomy.

The operation is simple and ordinarily not difficult; the after results are most brilliant — there are fewer adhesions, consequently there is less complaint of pain in the side; there are no persistent fistulæ. In other words, in ideal cases — that is, in cases which conform to the requirements of the conditions above — cholecystectomy may be regarded as a curative procedure, whereas cholecystostomy cannot be so regarded — it is a curative procedure in some cases but not in all. The position that the gall bladder should receive exactly the same treatment as the appendix is hardly tenable. There are, however, several points of analogy in the two organs.

I would then formulate my feeling with regard to the two procedures mentioned above in somewhat this fashion: Cholecystostomy should be done in those cases of gall-bladder and biliary duct surgery in which quick drainage is needed for the deeper ducts and in which the surgeon is not absolutely sure that the deeper ducts are entirely free. Cholecystectomy should be done in cases of acute cholecystitis, in cases of cholecystitis resulting in gangrene and empyema of the gall bladder, in small contracted (infected) gall badders which are functionally useless and which will not be of service in facilitating drainage, and in all cases in which the surgeon is morally sure that the deeper ducts are free from obstruction.

During an acute attack of gallstone colic it is wise to postpone operative interference. It seems to me that any patient having definite signs of gallstones or an inflammatory process about the gall bladder should be operated upon, and, in general, the earlier operative interference is instituted, other things being equal, the easier will be the operation from a purely technical point of view and the less will be the risk to the patient of the complications and sequelæ of gallstones.

The technique of cholecystostomy is facilitated by not suturing, in certain cases, the gall bladder to the parietal peritoneum, but by so securely fastening the drainage tube within the gall bladder that no leakage of bile takes place about it. The few adhesions arising from the gauze left beneath the gall bladder and tube serve to wall off the general abdominal cavity and cause little if any disturbance subsequently.

I. A. D., woman, forty-six years old, married. Patient of Dr. John Torrey of Andover, Mass. *Cholecystitis. Acute attack just over. No jaundice. Cholecystostomy, drainage of the gall bladder. Recurrence of symptoms after two years. Freedom from symptoms referable to the gall bladder now for another year.*

General health excellent. Six years ago was the first attack attracting attention to the region of the gall bladder. This attack was characterized by pain of moderate severity, referred to the left hypochondrium and then to the right hypochondrium, where it remained. The pain was relieved by hot water applications. It was attended by nausea. Each succeeding year up to the present time she has had a similar attack. The attack one year ago was more severe than any preceding; the pain not only was felt in the right hypochondrium but extended through to the right shoulder blade. During this past year these attacks have increased in frequency and severity, occurring every three months. These later attacks have been attended by severe vomiting. Both morphia and ether have been used to control the pain. After each attack soreness has been present under the right costal arch over the region of the gall bladder. The patient was seen just after one of these attacks. There was no jaundice.

Examination. A moderately stout, well-looking woman. She complained of pain beneath the right shoulder blade and gave evidences of tenderness over the gall bladder. Muscular spasm was present over the region of tenderness.

Operation. Peritoneum opened through the right linear semilunaris. A small amount of clear fluid in the abdomen. The gall bladder presented slightly enlarged, tense, its walls thickened but not friable. It contained a glairy, thick, ropy mucus. A granular sediment removed from the depths of the gall bladder and from the cystic duct, which was obstructed by this material. No stones were felt in any of the ducts. The gall bladder was fastened to the peritoneum, a rubber drainage tube was introduced into the gall bladder, and permanent drainage established. After some hours bile appeared in the drainage tube. The tube was removed after about ten days. The fistulus opening gradually closed and the patient made an uneventful recovery.

Subsequent history. For two years after operation the patient was perfectly well. Then she had an attack of pain and vomiting somewhat similar to the original attacks. The pain radiated to the right shoulder blade. Stools were normal. There was no fever. Pain was controlled by morphia. Now for one year she has been well, having a little mild distress at times in the right side. Her general health has been better than before operation. A thorough exploration of the biliary passages would be wise in this instance, and in the absence of calculi in the common and hepatic duct cholecystectomy would be indicated.

II. J. T., a man sixty-four years old, married. A patient of Dr. Coggswell, Cambridge, Mass. *Cholecystitis. Acute attack. No jaundice. Cholecystostomy. Persistent gall-bladder fistula. Second cholecystostomy and removal of stone in gall bladder and closure of fistula.*

Excepting for chills and fever and protracted diarrhea during the Civil War the patient has been well all his life. A little over forty-eight hours ago he was seized with a sudden, sharp, cutting pain across the upper abdomen. This pain was attended by vomiting. After the pain had first subsided he felt as if there were a tight constriction or band around his waist over the costal arch. He took castor oil, and a little later his bowels moved. The following day the

bowels moved again. He had severe pain throughout the greater part of the day and vomited once. Upon the third day there was a little less abdominal pain, but in the right hypochondrium, where the pain had been most intense, there was marked tenderness corresponding to the region of the gall bladder. Jaundice was absent.

Examination. The abdomen was slightly but uniformly distended and tympanitic all over and in both the flanks. To the right of the umbilicus and extending upward to the costal border a mass was felt which was tender. The liver was not enlarged. Rectal examination showed nothing of importance.

Operation. Under ether the mass felt in the abdomen was found to be continuous with the liver and moved upward slightly with inspiration. The peritoneum was opened through an incision to the outer border of the rectus. Considerable free clear fluid was found in the abdomen, and the culture from this fluid proved it to be sterile. There was found a gall bladder much enlarged, extending nearly to the umbilicus. It was covered with fresh fibrin and was slightly adherent to the surrounding parts, the ascending colon and the lateral abdominal wall. The gall bladder was attached to the peritoneum at the upper end of the incision, walling off gauze placed beneath it, a suture introduced into the fundus of the gall bladder for traction, and the gall bladder aspirated. Three ounces of thick, cloudy mucus was evacuated. The gall bladder was incised and inspissated bile was found in the depths of the gall bladder and cystic duct. Cultures made from the contents of the gall bladder were found sterile. The hand introduced into the abdomen found stones in the cystic duct. These were pushed upward into the gall bladder and removed; seven or eight of them faceted, the size of raspberries. No stones were found in the common duct. The gall bladder was drained by rubber drainage. The tube was removed in eight days. The patient was home in eighteen days, with a small fistula.

The following year, the sinus having remained open and there having been no pain nor jaundice, and the bowels having been regular, an operation for the closure of the fistulous opening was made by another surgeon and a small pocket near the fundus of the gall bladder, containing a slight amount of puriform material and three gallstones, was emptied. The gall bladder was again drained, the tube being removed after two days, there being a free flow of bile. The patient was discharged after two weeks with a small sinus.

After the first operation the flow of bile was very limited.

Subsequent history. One year after the last operation he is in perfect health. There has been no recurrence of the gall-bladder trouble. Fistula has closed. After working hard he feels pain or a pulling sensation at the site of the operation, but it amounts to comparatively little. A cholecystectomy might have been done very properly at either operation after the removal of all stones.

III. M. A., twenty-eight years old, a woman, married. *Gallstones, acute attack. No jaundice. Cholecystostomy, drainage. Small contracted gall bladder, many adhesions.*

She has two children, and has always been in good health. Five days ago she had an attack of severe pain in her "stomach," but did her work about the house. Two days ago pain of a similar character localized itself in the right side of the abdomen under the costal border, extending to the right shoulder blade. She vomited many times. There was no jaundice. The bowels moved naturally.

Examination. The abdomen was uniformly distended; the right half of the abdomen was rigid; there was marked tenderness in the right hypochondrium and to the level of the umbilicus upon the right side. No tumor could be felt. Vaginal examination discovered the uterus retroverted and lying a little to the right.

Operation. The peritoneum was exposed through an incision at the outer border of the right rectus muscle. The small intestine was found adherent to the anterior abdominal wall. The gall bladder was discovered beneath these adhesions as a rounded, hard, tense tumor extending to the level of the umbilicus. The gall bladder was incised, after protecting the parts about with gauze. The walls of the gall bladder were one-half inch thick, a glairy mucus was evacuated, and from the depths of the gall bladder came a puriform-looking material, and finally many small gallstones and two large stones. The culture from the contents of the gall bladder was the "bacillus coli communis." The gall bladder was attached to the peritoneum, a gauze wick below the bladder, rubber drainage of the gall bladder. Only a slight discharge of bile came from the gall bladder, and it was found that the tube was plugged by a few small stones, upon the removal of which the discharge became greater.

An uneventful convalescence; three weeks after leaving the hospital the fistulus opening closed.

Subsequent history. Cannot be found. The culture of the colon bacillus from the contents of a gall bladder shut off from the biliary circulation in the absence of jaundice need not preclude the doing of a cholecystectomy. Drainage in this case, however, proved apparently satisfactory.

IV. W. F., a woman sixty-six years old. Patient of Dr. Malcolm Storer, Boston, Mass. *Gallstone attacks. No jaundice. Cholecystostomy. Death from pneumonia.*

Twenty-five years ago she is said to have had typhoid fever; many years ago attacks of what was called gall-bladder colic. During the past two years and a half she has had many attacks. These attacks were associated with pain in the right hypochondrium, severe enough to double her up, attended by vomiting.

Examination. An old woman with moderately distended abdomen; an indefinable mass upon the right side under the costal arch, which was slightly tender. Jaundice was absent.

Operation. The gall bladder was found adherent to the anterior abdominal wall and to the transverse colon. The gall bladder was moderately enlarged. Upon opening it fifty stones were removed. The cultures from the gall bladder showed colon bacillus. The gall bladder was drained; bile appeared in twelve hours. On the second day the patient showed signs of a pneumonia,— the abdomen appeared normal,— and from this pneumonia the patient died.

V. C. A., a woman fifty-three years old, married. *Acute attack of gallstones. Jaundice. Choledochotomy. Cholecystostomy. Drainage. Recovery.*

For ten or twelve years she has had some stomach trouble, "dyspepsia." The bowels have been constipated. For one year she has been troubled each month by "bilious headache." These attacks have been attended by vomiting and jaundice, and she has noticed the stools have been clay-colored. She has never been severely jaundiced. Three days ago she had a sharp attack of pain in the right hypochondrium which she says resembled the bilious attacks which she has had during the past year.

Examination. The abdomen slightly distended;

no tumor felt. No especial tenderness over the region of the gall bladder, but at the mid-point of the abdomen, over the ensiform cartilage, there was marked tenderness. Incision at outer border of the rectus discovered a slightly contracted gall bladder adherent to the parts about. A small stone was found in this contracted gall bladder, and a large stone, larger than the end of the thumb, was found in the second part of the common duct, and was removed by incision through common duct, suture of duct. Drainage of gall bladder by rubber tube, gauze wick to common duct. Gradual closure of fistula Uneventful recovery.

Subsequent history. One year following the operation the report is that she has not been so well for years.

VI. N. G., a woman thirty-eight years old, married. A patient of Dr. Simpson of Boston. *Subacute attack of gallstones. No jaundice. Cholecystostomy. Recovery.*

Five months ago was the first attack, with pain in the region of the gall bladder. The pain radiated to the right shoulder. Since that time there have been frequent attacks lasting from two to nine hours. These attacks were attended by nausea and vomiting. At no time has there been jaundice.

Examination. The abdomen was generally soft, full and tympanitic. There was no unusual sensitiveness excepting over the gall-bladder region, where there was tenderness. No mass was felt.

Operation. Through the right semilunaris incision the gall bladder was found slightly distended, with some adhesions about it. No stone was felt in the ducts. The gall bladder upon being opened was found to contain thick, tarry biliary detritus and one small stone. Rubber drainage was used. The culture from the interior of the gall bladder showed many colonies of the bacillus coli communis. The color of the stools subsequent to the operation did not return to a normal condition immediately, but rather more slowly than usual. During convalescence there was some pain about the gall bladder and the costal border. The patient went home with a very slight sinus.

Subsequent history. After a few months the wound has closed. Has some pain at times referable to the right hypochondrium. Has had no acute attacks of gallstone pain similar to the attacks previous to the operation.

VII. C. B., a woman seventy-six years old, married. A patient of Dr. Mead of Winchester, Mass. *Acute attacks of gall-bladder pain. No jaundice. Cholecystostomy. Drainage. Recovery.*

Two months ago she had an attack of pain in the back of the neck and between the shoulders, and finally extending to the right hypochondrium, requiring morphia to relieve it. This pain was sharp and shooting in character. It doubled her up. She was somewhat chilly and hot, and distended, at the time of these attacks. She has had several each week since the first attack. The last attack was yesterday.

Examination. She was very thin, almost emaciated. The liver was not enlarged. There was no jaundice. There was slight tenderness and a little spasm over the gall-bladder region.

Operation. Incision at the outer border of the right rectus. No stone was felt in the gall bladder. A small stone was felt in the common duct. The gall bladder was opened and found to be very much thickened, contracted, and the stone felt in the common duct was pushed back and removed through the gall bladder. There were a few adhesions of the gall bladder to the neighboring parts. Drainage by rubber tube was used. A small amount of bile appeared, after a few hours, from the tube. Drainage was omitted and gradually the sinus was closed. The patient has had attacks of colicky pain in the bowels — "wind colic" — not like the previous pain. There has been no jaundice.

Subsequent history. During the past two or three months she has had more or less grumbling pain in the gall-bladder region, and a few weeks ago had quite a severe attack of pain resembling very much the passage of a gallstone. For several months now there has been no difficulty at all with the right side.

VIII. H., a woman fifty-four years old, married. She has had several children. *Cholecystitis. Subacute attack. No jaundice. Cholecystectomy. Recovery.*

She is said to have had "brain fever," pneumonia and at different times "pelvic abscesses." Two months ago she had a "bilious attack" accompanied by chills, backache and vomiting and pain, which extended from the right hypochondrium to the back and right shoulder blade. The present attack is of two weeks' duration and resembled the attack of two months ago. This attack was attended by much tympanites, nausea and needle-like pains extending from the navel through to the back and down to the right hip. During the past year she has had three attacks similar to this present one.

Examination. The abdomen was uniformly distended. In the right hypochondrium was a tumor which extended to beyond the median line and was continuous with the liver dullness. The tumor was movable, smooth and slightly tender.

Operation. Cholecystectomy. Drainage tube out upon the seventh day. An uneventful recovery. The contents of the gall bladder consisted of cloudy fluid, a few gallstones and inspissated bile.

Subsequent history. Three years after operation the patient has had no disturbance in the right side. She has, however, malignant disease, probably carcinoma, of the uterus, from which she is dying.

IX. I. C., woman thirty-nine years old, married. Patient of Drs. Abbott and Torrey, Andover, Mass. *Gallstone attacks. Temporary jaundice. Cholecystectomy. Recovery.*

She has no children and has had no miscarriages. Two years ago she had an attack of bilious colic. Every few weeks since that time she has had attacks of severe pain in the right hypochondrium attended by vomiting and temporary jaundice. She had lost some flesh during this period and was constipated.

Examination. A very stout woman with full abdomen presenting tenderness over the gall-bladder region. Conjunctivæ was slightly yellow.

Operation. Peritoneum was exposed by an incision through the middle of the rectus. No stone was felt in the common duct. A white, round, solitary stone was removed from the cystic duct. The gall bladder was small, thickened and edematous. There were many firm adhesions about the cystic duct. The contents of the gall bladder were mucus and a pasty bile sediment. No puriform material was found. The gall bladder was removed. A bit of omentum was placed over the stump of the cystic duct. Gauze drainage. Recovery.

Subsequent history. She has been perfectly well since the operation, now several months. Her general health has been better than for some years previous to operation.

X. A man thirty-five years old, married. Patient of Dr. Boucher, Watertown, Mass. *Gallstone at-*

tacks. Temporary jaundice. Contracted gall bladder. Cholecystectomy. Recovery.

For five or six years he has had attacks of abdominal pain. Lately this pain has been limited to the right side of the abdomen below the ribs, radiating to the umbilicus. These attacks have been attended by vomiting and slight temporary jaundice. The bowels are constipated. The attacks have increased in frequency and severity. The present attack has been a week in its duration. The pain has been very acute, necessitating morphia for its relief, localized in the right hypochondrium and attended by nausea, vomiting and chilly sensations.

Examination. Abdomen markedly distended; no tumor could be felt. There was tenderness on deep pressure over the region of the gall bladder. There was a slight yellowishness of the conjunctiva.

Operation. Peritoneum was exposed from the belly of the rectus. The gall bladder was with difficulty found buried in omental adhesions. A few stones were discovered just outside the gall bladder in a pocket within the omentum. The gall bladder was markedly contracted upon many stones. Cholecystectomy. Gauze and tube drainage. Recovery.

Subsequent history. Seven months following operation he is in perfect health. He has had no recurrence of former attacks and has no digestive disturbance. The scar is firm and there are no signs of hernia.

XI. G. F., a woman forty-nine years old, married. A patient of Dr. Leitch of Andover, Mass. *Persistent jaundice. Gallstone attacks. Contracted gall bladder. Cholecystectomy. Recovery.*

She has three children. Six months ago she is said to have had a severe attack of "dysentery"; otherwise she has been well. One year ago she was seized with a severe pain under the right shoulder extending down the side and around into the right hypochondrium. This attack was preceded by nausea. At no time has there been vomiting. During this past year attacks of a similar sort have occurred as often as each two weeks. These attacks have required morphia to relieve the pain. Occasionally she has had chills with these attacks. During the past few weeks she has lost some flesh, during this present attack her best weight being 198 pounds.

Examination found a stout woman with a large abdomen, rather flabby, not particularly distended. Slight tenderness was felt over the region of the gall bladder. Very little, if any, muscular spasm. Conjunctivæ and skin yellow; urine containing bile.

Operation. Peritoneum opened in the right linear semilunaris. A contracted gall bladder found. Stones in lower part of gall bladder and cystic duct and all deeper ducts free. Gall bladder removed. Drainage by gauze. An uninterrupted recovery.

Subsequent history. The operation was eleven months ago. She has gained over fifty pounds in weight since the operation. She says she is in fine condition, and has no trouble with her side excepting a tiny bit of tenderness in the situation of the scar.

XII. O. T., a woman twenty-five years old, married. A patient of Dr. G. G. Bailey of Ipswich, Mass. *Acute cholecystitis. No jaundice. Cholecystectomy. Recovery.*

A normal confinement four weeks previous to present trouble. Always has had some indigestion; otherwise well. Five days ago was seized with sudden pain in the right hyponchondrium. Vomiting; some fever. Considerable morphia was administered to relieve the pain. Pain was at the edge of the ribs on the right and then moved a little lower toward the umbilicus. No jaundice.

Examination. A nervous, rather thin, but not ill-appearing woman. Tongue coated. Moved herself rather easily in the bed. The abdomen was not distended. There was a muscular spasm on the whole right side of the abdomen. A distinct tumor was felt projecting below the right hypochondrium to the level of the umbilicus. This tumor did not move freely with respiration. The tumor was tender to pressure.

Operation. Peritoneum was opened to the right linear semilunaris. The tumor felt externally was found to be the distended gall bladder filled with clear mucus-like fluid. A yellow, sandy slime was found in the depths of the gall bladder and in the cystic duct. There were no old adhesions about the gall bladder. The foramen of Winslow was patent. There were no gallstones to be felt in the common duct. The gall bladder was removed. Tube and gauze drainage. Uninterrupted recovery. Pathological report: "Acute ulcerative cholecystitis. W. F. Whitney."

Subsequent history. Six months following operation there has been no difficulty with the right side and she is in good health: "My general health has not been so good for years as it is at the present time."

XIII. N. C., a woman thirty-two years old, married. A patient of Dr. G. G. Bailey, Ipswich, Mass. *Gallstones. Acute attacks. Contracted gall bladder. No jaundice. Cholecystectomy. Recovery.*

She had eight children. Ten years ago, she is said to have had typhoid fever. Over a period of two years, at intervals of about three months, she has had continuous pain in the right hypochondrium, colicky in character, extending to the middle of the back, lasting from a few hours to a day. This pain has been relieved by the taking of a cathartic. She has never been obliged to take morphia until recently. These attacks have increased in frequency and severity. The last attack was two weeks ago. The pain was very sharp, colicky, taking away her breath for the time. There was nausea, some vomiting and slight jaundice. Urine dark in color. Had lost some weight recently. Her best weight was 208 pounds.

Examination. A large, well-developed woman presenting a large abdomen with a tender area in the region of the gall bladder and a similar tender area in the back to the right of the vertebræ. There was no muscular spasm. No tumor was felt. The liver was not enlarged.

Operation. An incision through the right rectus discovered the gall bladder much contracted and bound by dense adhesions to the liver, to the large intestine and to the duodenum. The gall bladder was found full of slimy granular material; the cystic duct was dilated and plugged with a gallstone; the common duct was patent. The gall bladder was removed and cystic duct tied and gauze drainage used. All wicks were removed at the end of six days. The patient went home at the end of three weeks.

A gall bladder about 6 cm. in its greatest diameter, outer surface rough and covered with an old fibrinous exudate. The walls were thin and fibrinous and the cavity contained several small gallstones. The mucosa was almost entirely necrotic. Cholelithiasis.

Subsequent history. A few months following operation there has been no recurrence of the difficulty. She is in good health.

XIV. E. D., a woman fifty-four years old, married. A patient of Dr. Bump, Somerville, Mass. *Spontaneous biliary fistula. Cholecystostomy. Closure*

A SERIES OF CERTAIN GALL BLADDER AND BILIARY DUCT OPERATIONS.

No.	Sex and Age.	Operation.	Immediate Result.	Pathological Findings.	Symptoms and Signs.	Duration of symptoms referable to gall bladder, although some signs were obscure.	Previous Diseases.	Remote Result.
I.	Woman 46 yrs.	Cholecystostomy	Recovery	No stones, glairy mucus, pasty sediment.	No colic, gall-bladder pain, no jaundice.	6 years		For 2 yrs. no attacks of colic, then 1 attack
II.	Man 64 yrs.	Cholecystostomy	Recovery	Stones in cystic duct, thick mucus, inspissated detritus, culture sterile.	Acute cholecystitis, no jaundice.	48 hours	Diarrhea protracted Civil War.	Past 10 mos. immunity; general health good; no further attacks; feels some pulling at wound after work.
III.	Woman 28 yrs.	Cholecystostomy	Recovery	Few stones, mucus, puriform material, culture colon communis.	Gallstone colic, no jaundice.	5 days		Not found.
IV.	Woman 68 yrs.	Cholecystostomy	Died	Many stones, culture colon bacillus.	Gallstone colic, no jaundice.	Many years	Typhoid fever 25 years ago.	Died—pneumonia.
V.	Woman 53 yrs.	Cholecystostomy	Recovery	Stone gall bladder and common duct.	Gallstone colic, jaundice.	10 years		Well, no trouble one year after.
VI.	Woman 38 yrs.	Cholecystostomy	Recovery	Stone, thick tarry biliary detritus, culture colon bacillus.	Gallstone colic, no jaundice.	5 months		After few months no attacks; some discomfort in right side.
VII.	Woman 76 yrs.	Cholecystostomy	Recovery	Stone common duct.	Gallstone colic, no jaundice.	2 months		Grumbling right side mild attack.
VIII.	Woman 54 yrs.	Cholecystectomy	Recovery	Stones, cloudy fluid, inspissated bile.	Gallstone colic, no jaundice.	2 months		Well, no trouble for 3 years.
IX.	Woman 39 yrs.	Cholecystectomy	Recovery	No stones, mucus, pasty biliary sediment.	Gallstone colic, temporary jaundice.	2 years		Well, no trouble for several months.
X.	Man 35 yrs.	Cholecystectomy	Recovery	Stones, no fluid.	Gallstone colic, temporary jaundice.	5 years		Well, no trouble for 7 months.
XI.	Woman 49 yrs.	Cholecystectomy	Recovery	Stones, no fluid.	Gallstone colic, persistent jaundice.	1 year		Well, no trouble for 11 months.
XII.	Woman 25 yrs.	Cholecystectomy	Recovery	No stones, mucus, cloudy fluid, biliary slime.	Acute cholecystitis, no jaundice.	5 days		Well, no trouble for 1 year.
XIII.	Woman 32 yrs.	Cholecystectomy	Recovery	Stone cystic duct, slimy biliary detritus.	Gallstone colic, no jaundice.	2 years	Typhoid fever 10 years ago.	Well, no trouble for few months.
XIV.	Woman 54 yrs.	Cholecystectomy	Recovery	No stones, clear bile.	Biliary fistula, no jaundice.	18 months		Well, no trouble for four months.
XV.	Woman 26 yrs.	Cholecystectomy	Recovery	No stones, clear mucus, culture staphylococcus.	Acute cholecystitis, no jaundice.	4 days		Well, no trouble for few months.
XVI.	Woman 40 yrs.	Cholecystectomy	Recovery	No stones, clear bile.	Biliary fistula, no jaundice.	Many years		Well, no trouble for a month.

of wound. Gall-bladder pain. Temporary jaundice. Cholecystectomy. Recovery.

Eighteen months ago a biliary fistula established itself without operation, and one year ago an operation was done exploring this fistula. The fistula was dilated and it was found to connect with the cavity of the gall bladder, from which a stone the size of an English walnut was extracted. The gall bladder was attached to the skin and drained through a glass tube. Drainage was removed in eleven days. Three weeks later the wound closed. She was practically well up to three months ago, when she began to have cramp-like pain in the right side of the abdomen extending up to the nipple. This pain doubled her up, the paroxysm lasting some twenty-four hours. She has become recently jaundiced. The pain is attended by vomiting and nausea. She has lost some 30 lbs. in weight.

Examination. The abdomen is rather flat, tympanitic, with a slight dullness over the region of the lower border of the liver on the right side. There is marked muscular spasm and great tenderness over the gall-bladder region. There is a tender spot in the back. White count 19,000.

Operation. An incision through the belly of the right rectus. The omentum was found adherent to the abdominal wall and about the gall bladder. Gall bladder also adherent to the intestine and to the duodenum and to the upper end of the old incision. It was difficult to separate it from its adhesions. The gall bladder was very much elongated and looked and felt something like thickened intestine. It was opened and clear bile evacuated. No stones were seen. There were no stones in the ducts. The gall bladder was removed and a plastic of peritoneum placed over the stump. Two wicks for drainage. After operation there was considerable discomfort. The stomach was washed out with great relief.

The patient went home in about three weeks with a very slight watery discharge from a small fistulous opening.

Subsequent history. After four months this patient is perfectly well and comfortable. There is no difficulty with the right hypochondriac region. The wound is entirely closed.

XV. A. J., woman twenty-six years old, married.

Patient of Dr. Dow of Reading, Mass. *Acute cholecystitis following two cholecystostomies. Enlarged gall bladder. No jaundice. Cholecystectomy. Recovery.*

She had four children. Four days ago she was seized with a sudden pain over the gall-bladder region and vomited once. The following day the pain increased and she vomited again. Upon the third day of the attack there was less pain and no vomiting. Yesterday, the fourth day of the attack, there was no pain, but there was soreness in the right side upon moving in bed. The bowels moved after taking salts. There was no jaundice. There were no clay-colored stools and there was no dark urine. One year ago a cholecystostomy was done, and six months ago a second operation was done. At both operations gallstones were removed from the gall bladder.

Examination. A stout woman presenting a tympanitic abdomen somewhat distended and a mass the size of the fist in the region of the gall bladder, which moved with respiration. Underneath a cicatrix of the former operations. The abdominal wall was attached to this underlying mass. There was tenderness and muscular spasm over this mass.

Operation. An incision in the right semilunaris discovered a very much thickened and enlarged gall bladder filled with clear mucoid fluid. The deep ducts were free from stones. The gall bladder was removed; the cicatrix excised at the same time. Gauze drainage. Culture fluid from the gall bladder showed staphylococci. Patient went home after about four weeks having a small discharging sinus.

Subsequent history. The sinus has closed. After a few months has had no recurrence of difficulty. General health is good.

XVI. C. H., woman forty years old, married. *Symptoms of gallstones. Cholecystostomy. Stone in cystic duct removed, flow of bile. Drainage. Persistent biliary fistula. Cholecystectomy. Recovery.*

She has had attacks of epigastric pain for many years, at intervals of about five months. Severe cramp-like pain accompanied these attacks. She has never been jaundiced all these years. Laid up at these times three or four days. The last attack was four weeks ago. She has lost some weight, but not rapidly. Ten days ago she had dull epigastric pain, at first intermittently, but for seven days it has been continuous, in median line, two inches below ensiform cartilage, never colicky or cramp-like. No chill. Vomited greenish material several times. She has never vomited blood. For one week her skin and conjunctivæ have been yellow. The urine has been dark. Stools have been green. Now the pain extends from the median line out to the region of the gall bladder and back to between the shoulders.

Examination. Poorly nourished. Abdomen not distended, tympanitic excepting at ninth costal cartilage, where there is a limited dullness and corresponding muscular spasm. The edge of the liver is not to be felt.

In May cholecystostomy. Stone removed from the cystic duct. Bile then came from deep passages. No stone in the common duct. Small gall bladder. Coagulation time,—four minutes. Wound solid in June.

Operation in September for persistent biliary fistula. Incision through right rectus. Adhesions between omentum, intestine and abdominal wall. Gall bladder found attached to the abdominal wall. Cholecystectomy. One wick to stump of the cystic duct. A slight biliary fistula existed for a few weeks.

One month after operation biliary fistula closed. Wound granulating and nearly closed. Never better health for years.

Clinical Department.

A CASE OF PYLORIC STENOSIS IN AN INFANT.

BY CHARLES W. TOWNSEND, M.D., BOSTON.

ALTHOUGH this affection has been reported more frequently of late years, the difficulties in the way of an early diagnosis make it desirable to throw as much light as possible on the subject by the report of cases.

The following case was seen frequently in consultation with Dr. A. E. Rogers. We had also the advice of Drs. C. P. Putnam, J. L. Morse, Rotch, Ladd, A. Thorndike and J. C. Munro.

A. B., male, born Aug. 22, 1903, weighed seven pounds. After ten days on the breast, the supply failing he was placed on modified cow's milk and progressed well until Sept. 12, at which time he weighed eight and one-half pounds. During this time he was having three or four stools daily and there was no vomiting. On Sept. 12, at the age of three weeks, he began to vomit occasionally at first, but with increasing frequency, so that on the 22d of September he was vomiting every fifteen minutes whether food was given or not. Early in October it was evident that by careful feeding it was possible for the baby to retain its food for several hours, but at the end of that time, the stomach contents would be forcibly ejected, sometimes to a distance of several feet. At times he would continue for several days with practically no vomiting, as was the case from the 16th to the 19th of October, on barley water containing a few drops of cream gradually increased in strength. In fact nearly every change succeeded for a while, but the vomiting always recurred eventually. Various weak formulas of cow's milk and whey modified with water, barley water or dextrinized barley were used, as well as the milk of a wet nurse, sucked by the infant from the breast, or pumped out and diluted with water or barley water. Barley water alone, albumen water and meat juices and broths were all tried, but with all the vomiting was sure to return. Bicarbonate of soda in grain doses every hour was given by the mouth, apparently with good effect at times. Bismuth and pepsin had no effect. Bromide by the rectum and bicarbonate of soda in large doses were also used without avail. Lavage also proved useless. When much reduced, salt water infusions under the skin helped to make up the deficiency of fluid in the blood.

After the first it was found impossible to nourish the child or even give medicines by the rectum, as any manipulation in that region brought on vomiting. During most of the illness, especially when vomiting was most severe, there was some tetany, as shown by the drawing in rigidly of the thumbs to the palms of the hands. The vomitus during the first few days contained bile, but never after this. At no time was there mucus or evidence of indigestion, the food sometimes coming up exactly as it went down, at other times showing the effect of acid digestion. The stools, although scanty and far between, as might be supposed from the small amount of food passed beyond the stomach, showed perfect digestion.

From the 27th of October to Nov. 5 the baby did excellently on top milk modified by dextrinized gruel. The stools were large and well digested, and although vomiting never entirely ceased he began to lose his pinched and atrophied appearance. His spirits were

good and everything seemed to point to his recovery. As vomiting returned in force, however, he was put back on dextrinized barley water alone and milk gradually added. With varied fortunes he continued until Nov. 16, when the propulsive vomiting returned as badly as ever. At no time until the 17th could anything abnormal be felt in the abdomen, which was rather flat. At that time a hard tumor could be felt in the epigastrium, and peristalsis of the stomach was made out.

From early in the case it seemed to us that it was one of spasmodic pyloric obstruction, with no evidence of gastric indigestion, or of organic stricture. The intervals of apparently nearly complete recovery with cessation of vomiting and good dejections seemed to negative the latter idea.

With the last return of vomiting it seemed unwise to wait longer, but to submit the child to an exploratory laparotomy at least, before it should succumb from starvation. With this Dr. J. C. Munro agreed. The appearance of a tumor in the epigastrium of course confirmed this decision. On Nov. 19 Dr. Munro performed gastro-enterostomy. The baby rallied well from the operation, but died twenty-three hours later of exhaustion.

A report of the examination of the organs by Dr. G. B. Magrath follows:

Specimen consists of stomach; esophagus and part of lesser curvature absent, with attached segment of small intestine, received in formalin. Length of cardia to end of pylorus 6.5 cm. Length of pylorus 1.5 cm. Diameter of pylorus 1.3 cm. Pylorus is thick, firm and rigid; its lumen is thick, — having been opened, — probably 2 to 3 mm. in diameter. Upon section its walls are about 6 cm. in thickness, the outer two-thirds consisting of a transparent layer 3 to 4 mm. across. The mucous membrane at the gastric end of the pyloric canal, thick and folded. Attached to sutures to the posterior wall of the stomach is a segment of small intestine; the organs in communication from an anastomotic opening, 1.5 cm. in diameter, with roughened edge. The union of the wound structures is firm and in part due to adhesions.

Microscopical examination of sections from the wall of the pylorus at about its middle portion shows extensive hypertrophy of the muscle coats: the muscularis mucosæ shares in this to a slight extent, but the greater part of the thickening is due to increase in the outer muscle coats. The mucous membrane presents a prominent fold but is otherwise not remarkable.

Diagnosis. Hypertrophy of the pylorus with associated narrowing of its lumen. Gastro-intestinal anastomosis.

Summary: An infant, healthy at birth, began to vomit at the end of three weeks. By careful regulation of the diet the vomiting improved at intervals, but as often returned. The vomitus showed no signs of gastric indigestion; it was projectile in character and often made up of several feedings. Constipation was a feature, but the stools when passed were normal in character. Emaciation became extreme. A visible and palpable tumor appeared in the epigastrium with dilatation and peristalsis of the stomach.

Gastro-enterostomy was performed successfully as regards the operation, but death ensued in twenty-three hours, at the age of three months, after an illness of ten weeks.

The autopsy showed hypertrophy of the pylorus, chiefly of the outer muscular coats, with narrowing of the lumen.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR SURGERY.

A MEETING for this section was held at the Medical Library on Wednesday evening, Dec. 2, 1903.

DR. F. B. HARRINGTON was unanimously elected Chairman for the winter and at once took the chair.

The section, after discussing the question of holding regular meetings this winter, voted unanimously that meetings should be held and that the details of arrangements be left to the President and Secretary.

The chairman then introduced the general subject of discussion for the evening:

SURGERY OF THE GALL BLADDER.

DR. F. B. HARRINGTON: The surgery of the appendix vermiformis is now ancient history compared with the surgery of the gall bladder; yet the surgery of the gall bladder and the gall ducts is perhaps even more important, certainly it is more difficult than the surgery of the appendix. The pursuit of the appendix frequently led to the gall bladder in supposed cases of appendicitis. The evil effects of gall-bladder disease and of gallstones are very wide spread. It affects, not only the liver and the various bile ducts, but the stomach, the pancreas and the intestines, producing at times in these organs conditions, which if not relieved by operation, may be fatal. Thus we have intestinal obstruction from gallstones or from bands and adhesions, the result of pericystic inflammation. We may have acute pancreatitis and fatal hemorrhages from this cause, or we may have stricture of the pylorus from bands and perigastric inflammation, resulting in gastric obstruction and dilatation. We may have cholangitis and hepatic obstruction from the same cause.

It is a rule, almost without exception, to remove the appendix when operation is called for in all forms of appendicitis. What shall we do with the gall bladder? We cannot argue because the appendix is better out than in that the gall bladder is better out than in.

There are conditions in which all would agree that it is unwise to perform cholecystectomy as, for example, the obstruction of the common duct by inoperable malignant growth, where, by uniting the gall bladder to the duodenum or the colon, drainage for the bile can be obtained. Again, many would say in empyema of the gall

bladder, or in cholangitis, that drainage of the gall bladder was the safest and wisest course. The gall bladder is the origin of the trouble, and if it could be removed without harm of any sort, present or future, it would be better out of the way. Gallstones form from inflammation and infection, but only where there is stasis in the biliary current. If gallstones form in the smaller hepatic branches, such formation will be secondary to inflammation and obstruction lower down.

These considerations lead to the questions which have been printed in the call for this meeting.

WHAT ULTIMATE DAMAGE MAY BE DONE BY REMOVAL OF THE GALL BLADDER?

WHEREIN IS THE RISK OF CHOLECYSTECTOMY GREATER THAN THAT OF CHOLECYSTOSTOMY?

IN HOW MANY CASES OF CHOLECYSTOSTOMY HAVE YOU KNOWN A SECOND OPERATION TO BE NECESSARY?

DO GALLSTONES EVER FORM IN THE OTHER BILE PASSAGES AFTER REMOVAL OF THE GALL BLADDER?

DR. A. T. CABOT said perhaps the easiest way to state his feeling as to the wisdom of cholecystectomy was to enumerate the cases in which he should not do the operation. In cases of infection of the bile ducts in which drainage seemed to be a necessary part of the treatment, he would keep the gall bladder for that drainage, especially in cases of chronic pancreatitis, which have been shown to be so greatly benefited by a long drainage of the biliary passages. He would also leave the gall badder in a case of cholelithotomy, where he was doubtful whether all of the stones had been removed. He would also leave it in acute cases of gall-bladder inflammation, where the end of the gall bladder was readily accessible, and where everything was tied up in such a way as to make the separation of adhesions a serious additional risk to the operation. He reported cases in which he showed that removal of the gall bladder was wise for biliary colic, depending on kinks of the gall bladder, or of the gall ducts.

Dr. Cabot's practice has been steadily tending in the direction of taking out more and more gall bladders. He recalls only one case where gallstones actually re-formed after a case of cholecystostomy. He had met several cases operated upon by other surgeons, and also by himself, in which stones not found at the first operation had been taken out later. He believed that in most of these cases the stones were concealed in the hepatic ducts, and, therefore, not found at the first operation. With the gall bladder removed, he thought the conditions less favorable for the future formation of stones, as the place where stasis of bile occurred would be removed.

DR. H. O. MARCY spoke briefly of the history of gall-bladder surgery in Boston and of the likelihood of its development in the near future. He also mentioned some interesting cases of choledochotomy.

DR. F. B. LUND stated that the question of removal of the gall bladder did not depend so much on the ultimate effect on the patient, as it was well known that the removal of the gall bladder apparently did not affect the general health, but the question to be considered in regard to the removal of the gall bladder rather was, whether it was immediately the safest course for the patient.

Gangrenous, thickened and cystic gall bladders, which were apparently incapacitated from emptying themselves of bile, would better be removed in the majority of cases, but in ordinary gallstone operations, where the gall bladder showed little or no abnormality, except that it contained stones, the organ would better be left. Stones in themselves are evidence, not only of stasis, but of infection in the gall bladder, and wherever infection exists in the gall bladder or ducts drainage of the ducts is fully as important a matter as the removal of the stones. This can be more safely accomplished by using the gall bladder as a tube to drain the ducts than by removal of the gall bladder and tying a tube in the cystic or common duct. Wherever it is known that there was infection of the ducts, drainage is imperatively demanded and best accomplished by cholecystostomy. Wherever it is suspected that the ducts are infected — and this class will include the larger number of gallstone cases — cholecystostomy, with drainage of the gall bladder, is safer than cholecystectomy. After cholecystectomy, it is safer to provide drainage of the cystic duct, and in case of doubt, where there are stones in the common duct, to open that duct and drain it, whether stones can be felt or not.

Suture of the common duct is always a dangerous practice, and whenever it is incised it should be drained freely by tying in a full-sized tube. Some gallstones in the common duct may be impossible to feel, because the duct is so distended and its walls so thickened that the light stone floating in the fluid makes no impression on the finger. Wherever there are symptoms of common duct stone, and the duct is found dilated, even if no stone can be felt, it should be opened, and the stone will generally be found. Cases illustrating this point were briefly related.

DR. E. W. CUSHING: In considering the question of removing the gall bladder, the analogy with ablation of the appendix must not be pushed too far, for while the latter is apparently an organ with little or no function in the human race, and a mere anatomical survival, useless and prone to degenerate, the gall bladder has a definite function. It is clear that a continual discharge of bile into the intestine is not requisite or desirable and that the gall bladder not only serves as a reservoir for the storing of bile until it is needed in digestion, but that as a flush-tank it can at intervals expel its contents in such a way as to clear the bile duct of infective agents, which are always trying to enter from the intestinal canal.

If, then, the condition of the gall bladder is such that it can resume and exercise its proper function, it is best to preserve it, and the burden of proof is on those who would advocate its removal. The operation of cholecystectomy is not yet old enough for us to know what disadvantages may ultimately follow from loss of a functioning gall bladder, although it is of course conceded that it is better to remove this organ when it is functionless, hopelessly diseased and a source of danger in itself. In regard to the comparative danger of the two operations, it seems to me that although in selected cases, and in the hands of expert operators of large experience, cholecystectomy is as easy and as safe as cholecystostomy, yet in patients who are fat and feeble, or whose systems are oppressed with biliary absorption, the latter operation is very much easier and safer. It must not be forgotten, moreover, that these operations must be done by many surgeons who are not particularly expert and have no very wide experience, for as things are going now in the multitude of small hospitals perfectly ideal conditions do not always prevail.

Moreover, when the gall bladder is removed and its duct is tied, we lose the advantages of free drainage, which may be required by the condition of the common or hepatic ducts, or by the presence of stones in these ducts which have not been detected at the operation. It is well known that such overlooked stones will find their way out when the gall bladder is attached to the abdominal wall and drained. I have known stones impacted in the common duct, and detected but not removed at the operation, owing to the grave condition of the patient, to find their way out safely weeks afterward. I have known only one case in which stones kept coming out for over a year, thus keeping open a mucous fistula, communicating with the gall bladder. In this case, however, all the stones were small and had sharp edges, and were apparently pieces of a large stone, which had been broken in dislodging it at the time of operation. The fistula finally closed without subsequent trouble. I have no knowledge of my own as to whether gallstones ever form in the other biliary passages after removal of the gall bladder.

Dr. J. C. Munro agreed with Dr. Cabot in the importance of preserving gall bladders that would eventually return to a normal condition, especially on account of the value of the gall bladder as a drain for the pancreas. He had known of four of his cases which required another operation after cholecystostomy. He could not tell whether stones had re-formed or had been left in the bile passages at the original operation. In three of these he had performed the original operation. He always guided his decision by a suggestion of Mayo's, that the gall bladder should be removed if it were functionless, as in gangrene, obstruction of the cystic duct, or atrophy. He was strongly in favor of not removing normal gall bladders, *i. e.* those which could perform their function, or when the surgical indications at time of operation pointed to an unjustifiable risk in removal of the gall bladder as contrasted with simple drainage.

The question for discussion was, not whether a gangrenous or a malignant and totally useless gall bladder should be removed, but whether an otherwise normal organ, except for the presence of gallstones alone, should be removed or drained. For his part, he still believed in preserving and utilizing such gall bladders.

Dr. Frederick Winslow: I have been studying the end results of all the gall-bladder operations done at the Massachusetts General Hospital from January, 1894, to January, 1903, and think that the bare unvarnished facts in figures may throw some light on the relative value and danger of cholecystostomy and cholecystectomy as operations *per se*, although in the majority of the unsuccessful cases of either kind, the untoward results are due, not to what is *done* to the *gall bladder*, but to what is not done to the deeper biliary passages.

Excluding 13 for malignant disease there were 170 cholecystostomies. Of these 21 died a few days after the operation; 27 came to a second operation; 29 are unrelieved from one to five years after operation; 4 have had fistulas two to four years without symptoms; 46 have been well one to seven years, save for very slight occasional symptoms; and 43 have not been heard from since leaving the hospital. Excluding two for malignant disease, there were 44 cholecystectomies. Of these 9 died within a few days after operation; none came to a second operation; 2 died with symptoms unrelieved, one ten months, the other two and a half years after operation; 2 (in which the choledochus was drained) have been relieved, but still have fistulas one and one and a half years later; 22 have been completly relieved, one to nine years; and 9 have not been traced since leaving the hospital.

It will be noticed from these figures that although the mortality of the cholecystectomies is 20.4% (9 out of 44) while that of the cholecystostomies is 12.3% (21–170), yet, on the other hand, the percentage of cholecystostomies which have been completely cured is but 36.2% (46–127), while for the cholecystectomies it is 62.8% (22–35). This is certainly significant of much, in spite of the dictum, often enough true, that *la statistique est la mensonge en chiffres;* and cholecystostomy must be regarded as an emergency operation only, an elementary and preliminary performance, one which in itself cures only one out of every three cases.

Dr. S. J. Mixter: The subject of gall-bladder surgery is always an interesting one, especially as there are many points in technique and choice of operation that are far from being settled. The point that has been of perhaps the greatest interest to me is the question of the removal of the gall bladder, and I find that I have gradually come to a view where I seldom leave it. There is no doubt but that drainage

will serve in many cases of acute or chronic infection, either with or without stones, but I find that there is little if any more risk in the more radical operation, and that the results seem on the whole more satisfactory.

At first I removed only those that were greatly thickened, where perhaps the stones were so imbedded in pockets in the wall that their complete removal was almost an impossibility. The next step was the removal of the small contracted ones, so often found containing a single or few stones and deeply buried in adhesions; acutely inflamed and gangrenous ones came next; and, finally, the comparatively normal organ containing a stone or stones.

The greatest objection that has been made to cholecystectomy, aside from its greater difficulty, has been that drainage is more difficult. Now I have never seen a case where it was not possible to get good drainage by means of a rubber tube passed through the stump of the cystic duct, or into the common duct when that had been opened. A ligature or suture holds the tube in place and a packing of gauze protects the abdominal cavity.

In suitable cases where the abdomen is opened for any reason, I make it a rule to examine the gall bladder by touch, and if stones are felt, the condition of the patient being good, I close my incision in the usual manner if it be a low one and expose the gall bladder by the usual incision. For the past two years I have removed such gall bladders without opening them, and never have had occasion to regret it. Gauze drainage has never been omitted.

As regards the subsequent history of the patients, I can say that I have never seen a case where the loss of the gall bladder has been the cause of any unpleasant symptoms, and there have been no recurrences of attacks and not nearly so much complaint of the pain caused, I suppose, by the pull of the scar on the gall bladder following drainage.

In gangrenous inflammations the results are perhaps the most thoroughly satisfactory. In one case while removing such a gall bladder which had not perforated, a large abscess was found in the liver, or between it and the liver, the patient making a rapid recovery. There is one class of cases in which I have always left the gall bladder and perhaps always shall, that is, in pancreatitis.

There is no doubt but that the operation of cholecystectomy is more difficult than that of simple opening and tying in a tube, and hence the inexperienced surgeon should choose the less dangerous operation; but I am sure that in the hands of quick and experienced men the operation of cholecystectomy will become largely the one of choice.

DR. E. A. CODMAN showed four gall bladders which he had removed because of stones impacted in the cystic duct. Two had made perfect recoveries. One of the others was complicated by the presence of a fistulous opening between the gall bladder and duodenum, stones in the hepatic and common ducts and an abscess between the gall bladder and liver. This gall bladder was exceedingly small. The case eventually died from leakage of the duodenal suture.

The fourth case was interesting as showing that gallstones may form again after cholecystostomy. Dr. Codman had done the latter operation on this patient two and a half years ago. Complete relief had followed for six months, and then very severe symptoms began again and the patient rapidly lost ground. Owing to her persistent vomiting, nourishment was almost impossible. Though she had greatly abused morphine, it was felt that there must still be some trouble with the gall bladder. At times she had attacks of jaundice and pain. One year after the first operation he therefore removed the gall bladder. The specimen shows a stone impacted in the cystic duct and the gall bladder filled with stones of entirely different appearance from those removed at the first operation.

This patient was unable to retain any nourishment after the operation, vomited incessantly and died at the end of three weeks. The autopsy showed no adequate reason for death except the emaciation due to starvation.

He thought that since he could detect no stones in the common duct at the original operation, and since at the second operation he found the cystic duct occluded with a very small stone, although the stones in the gall bladder were large, and since at the autopsy only three weeks later no stones whatever were found in the common or hepatic ducts, the only rational conclusion is that all the stones were formed in the gall bladder. He believed that had he done cholecystectomy at first he would have saved the patient. When in doubt he thought it was wise to remove the gall bladder.

DR. F. B. HARRINGTON: The absence of the gall bladder and its functions, as far as I have observed, is not injurious to the individual after recovery from cholecystectomy. Some surgeons with large experience in cholecystostomy state that gallstones do not re-form — Robson, Mayo and Kehr. Other surgeons report cases of re-forming gallstones. I have had myself three cases where a year or more after cholecystostomy and drainage attacks of colic and jaundice have recurred, suggesting the passage of gallstones. Dr. Codman has shown us here tonight a gall bladder removed a year or more after cholecystostomy, in which gallstones totally unlike the original ones were found. I doubt if sufficient time has elapsed to determine definitely how frequently re-formation of gallstones occurs in a gall bladder which has been drained. I believe that a gall bladder which has once developed gallstones may do so again.

At the present time I feel that in uncomplicated cases, that is, on the discovery of a gall bladder with gallstones, whether the cystic duct be open or not, and with a patent common duct, that I am doing better surgery to remove

the gall bladder, no matter how nearly normal it seems. I think one should always allow for possible leakage, leaving a gauze drain down to the stump for one, two or three days. In cases of acute cholecystitis and cholangitis without obstruction, I should be governed largely by the condition of the patient in deciding whether the gall bladder should be removed or not. If tubage of the common duct is as satisfactory as described by Kehr, I cannot see the advantage of drainage by the gall bladder except to save time. I think that an objection to bringing the gall bladder to the surface exists because this drags upon the common duct and may cause kinking of the duct.

I have a case of cholecystostomy in which the gall bladder apparently is occasionally caught in a hernial opening of the scar. This causes extreme suffering, which is not relieved until what seems to be the gall bladder is pushed back through the hernial opening by pressure. On one occasion in this patient's case, an attack of this sort has been followed by temporary jaundice, which I think may have been due to obstruction from kinking by the pulling of the gall bladder on the common duct. While I do not believe in the removal of the gall bladder in every case. I should advise its removal in a majority of cases of disease of the gall bladder and bile ducts due to gallstones.

Dr. J. W. Elliot and Dr. H. H. A. Beach were not able to be present at the meeting, but have contributed the following expressions of their opinions for publication.

Dr. J. W. Elliot: The ultimate damage done by removal of the gall bladder may be of two sorts. In the first place, we do not know the exact function of the gall bladder, and therefore it may prove more important than we at present suppose. I do not believe that surgery is likely to improve the normal human body. Witness the growth of opinion in favor of myomectomy as against hysterectomy and in favor of conservative operations on the tubes and ovaries and other organs. The second sort of damage may come from its injudicious removal when there is a stone or disease in the common duct. Patients are often sent to surgeons in the later stages of gallstone disease, with profound cholemia or severe cholangitis, and with more or less diseased liver and kidneys, in a condition very unfavorable for a severe surgical operation. In such cases I believe a preliminary cholecystostomy, with drainage of the ducts and liver through the gall bladder, will be attended with a considerably lower mortality than the immediate removal of the gall bladder, with drainage of the common duct direct. In cases where cholecystectomy has been done and symptoms of cholangitis continue or jaundice appears, we have no choice but to drain the common duct, regardless of the patient's condition.

Speaking simply of the technique of the operations I think cholecystectomy is as simple as cholecystostomy, and should have about the same mortality. If the mortality is higher in cholecystectomy it is probably due to some of the reasons given above. I have known a second operation to be necessary in quite a number of cases of cholecystostomy, but as the operation in most of these cases was intended to be only preliminary and often life-saving, a second operation naturally followed. I have also occasionally made the mistake of trying to save a gall bladder too much diseased, which proved to be troublesome and therefore had to be removed later.

I do not know if gallstones ever form in other bile passages after removal of the gall bladder, but I have often found them in the hepatic and common ducts when there were no signs of their ever having been in the gall bladder, and in one case I remember finding hundreds of small stones in the hepatic duct and liver with a normal gall bladder. In this case the stones were evidently forming in the liver.

For the reasons given above I do not believe in the almost routine practice among certain surgeons of removing a moderately distended gall bladder without even opening it or examining the deep ducts. The reasons given in favor of such a procedure are that it is usually less trouble to the patient and that stones do not re-form after removal of the gall bladder. The argument against it is that in many cases of gallstone disease we cannot be certain of finding all the stones, and there is often more or less cholangitis present, which conditions are best treated by drainage; and drainage is usually safer by cholecystostomy. If we are able to give up drainage in a simple case where the gall bladder is nearly normal, I prefer "ideal" cholecystostomy to cholecystectomy. In regard to the re-formation of stones I have reason to believe that they very rarely recur after cholecystostomy.

I think cholecystectomy should be only done when the common duct is clear and there is little or no cholangitis. It is indicated when the gall bladder is so diseased that its normal condition is not likely to be restored, or when there is an irremediable obstruction of the cystic duct. In acute phlegmon or gangrene of the gall bladder it is usually safer to do a preliminary cholecystostomy, packing gauze around the sloughing gall bladder, and later when the acute process has subsided a cholecystectomy. All the cases I have managed in this way have recovered.

Dr. H. H. A. Beach: Gall bladders demanding surgical treatment are in a large proportion infected. The degree of virulence and extent of infection in and beyond the gall bladder varies, whether the infection proceeds from the liver or ascends from the intestine. The certainty of completely removing all infection by cholecystectomy must be conceded, if the patient is to lose so valuable an outlet for drainage as the intubed gall bladder. The damage that may be done through rousing into activity an infected territory by an operation without providing adequate drainage is incalculable,

even if the hepatic and common ducts have already been distended by the passage of the stones.

The risk of cholecystectomy is the uncertainty of completely removing infection by the operation. Its great advantage to the patient is in lessening the liability to cancer by the excision of tissues that have been the seat of chronic inflammation. A second operation after cholecystostomy has been necessary in three of my cases, on account of pain or pain associated with jaundice. The first operations had been performed by surgeons of large experience. In one instance drainage had been maintained for five months. I have never seen but one permanent biliary fistula from a drained gall bladder. In that instance the common duct was completely shut off from the intestine by a large mass of adhesions and the patient refused a cholecystenterostomy.

Recent Literature.

Diseases and Injuries of the Eye, with their Medical and Surgical Treatment. By GEORGE LAWSON, F.R.C.S. (Eng.), Consulting Surgeon to the Royal London Ophthalmic Hospital, etc. Sixth edition with 249 illustrations. Revised and in a great measure rewritten by ARNOLD LAWSON, F.R.C.S. (Eng.), Assistant Surgeon to the Royal London Ophthalmic Hospital, etc. pp. 587. London: Smith, Elder & Co. 1903.

As the last edition of this work was published in 1885, it is obvious upon reading its pages that the new edition has, as its title page says, "been largely rewritten."

It is now a satisfactory texbook of the present period, although in some instances it has not been quite brought to date, according to American standards. The description of the technique of ophthalmic operations is by far the best part of the book, and is superior to that in any general textbook on the eye that has been recently published. The print and paper of the book are good. The index, which is unusually full, occupies forty-six pages, which makes it particularly valuable as a handy reference book.

Diseases of the Stomach. A Textbook for Practitioners and Students. By MAX EINHORN, M.D., Professor in Clinical Medicine at the New York Post-Graduate Medical School and Hospital, Visiting Physician to the German Dispensary. Third revised edition. New York: William Wood & Co. 1903.

The ingenious inventor of many of our modern gastric instruments stamps his personality very strongly upon this book. Apart from the sections devoted to descriptions of the author's apparatus, the volume on the whole is concise and practical. We regret the introduction by the author of so many new terms in his descriptions of diseases of the stomach, because they tend to create the feeling among general practitioners that the study and treatment of gastric affections is far more difficult than is really the case.

Textbook of Diseases of the Eye, for Students and Practitioners of Medicine. By HOWARD F. HANSELL, A.M., M.D., Clinical Professor of Ophthalmology, Jefferson Medical College, etc., and WILLIAM F. SWEET, M.D., Demonstrator of Ophthalmology, Jefferson Medical College, etc., with chapters by CHRISTIAN R. HOLMES, M.D., CASEY A. WOOD, M.D., D.C.L., and WENDELL REBER, M.D. With 256 illustrations, including colored plates. pp. 532. Philadelphia: P. Blakiston's Son & Co. 1903.

This textbook is one of the most satisfactory put forth in recent years. The text is concise, clear and judicial. Old and disused forms of treatment have been entirely omitted; modern methods of diagnosis and treatment have been emphasized and given first place. New methods which have not yet established themselves have been treated justly, but their tentative positions duly emphasized. The illustrations are good and, with few exceptions, new. The type is clear and the page of convenient size. The index is full and accurate.

The Purin Bodies of Food Stuffs; and the Rôle of Uric Acid in Health and Disease. By I. WALKER HALL, M.D., Assistant Lecturer and Demonstrator in Pathology, the Owens College; formerly Senior Demonstrator in Physiology at the Owens College, Victoria University of Manchester; Honorable Pathologist to the Salford Royal Hospital. Second edition (revised). London, W. C., and Manchester: Sherratt & Hughes. 1903.

This book consists chiefly of an account of the author's own work. In it he gives a series of analyses of the various food stuffs for purin bodies, which is more complete than has heretofore been published. The presence of purin bodies was demonstrated in beers and ales and their absence shown in wines, which accounts for the increased excretion of uric acid after the former. It is noteworthy that purin bodies do not alter the blood pressure in rabbits, because this tends to show that one of the many unproved assumptions of Haig is wrong. Haig attributed headache, migraine and many other diseases to the presence of purin bodies in the blood, whereby, as he says, the blood pressure is raised. The work of Burian and Schur on the quantitative effect of purin bodies of the food on those of the urine is confirmed. The metabolisms of purin bodies in health is considered as well as the effect of drugs on the uric acid in the urine in health and disease. Hall's critical study of the methods employed for the determination of purin bodies is valuable.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, FEBRUARY 11, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

INTERSCHOLASTIC SPORTS.

INJURIES and accidents due to *college* sports have been for many years a favorite theme for the public press. The number and seriousness of such injuries have usually been much exaggerated, though of course there has always been a certain basis of fact for such statements. During the past decade, however, *interscholastic* sports have come into existence and have developed with marvelous rapidity. In these school sports there are real and potent possibilities of danger which are none the less important because they have largely escaped recognition. To these dangers it is high time to call attention and to suggest measures which shall diminish and, if possible, eliminate them.

It may be taken for granted that healthy boys will play games and follow sports, some of which will be rough, some dangerous and some neither rough nor dangerous, requiring skill and dexterity, rather than strength and courage. It would be most unfortunate, even if it were possible, to eliminate the rougher and in certain respects the more dangerous forms of amusements from the boy's life. We can, however, protect him from unnecessary and unjustifiable perils, and we may also exercise a considerable control in the choice of sports and in the manner of their practice. It certainly is no longer justifiable to allow interschool athletics to continue with the lack of supervision which has characterized them in the past.

These school sports have several elements of danger, and it may be said at the outset that the least of these are the bruises, sprains or even fractures which result from such games as football and basket ball. Such injuries are bound to come to active boys, and are of comparatively slight importance. The serious dangers are those of the heart and circulation, the general nutrition and probably, also, the nervous system. The factors which tend to develop and exaggerate these dangers are also numerous. They consist, first, of the unbounded and unquenchable enthusiasm by which the school sports are characterized; second, the immature age and the undeveloped physical condition of the contestants, who range from fourteen to eighteen years; third, the almost complete absence of medical supervision; fourth, the presence of either professional, or very young graduate, coaches, both of whom overlook the fact that their charges are young boys and not young men; fifth, the almost complete absence of age classification, that is, boys of fourteen years may be pitted against others of eighteen; sixth, the definite tendency of a large majority to contest in two, three or even four branches of sports, which follow one another chronologically and with almost no intervening interval of rest.

The writer would submit the following opinions, which probably will not be criticised as being radical or extreme: Cardiac hypertrophy of a degree characterized by an apex beat in the sixth space, an inch outside the mammary line, is not a desirable thing in boys not yet old enough to enter college; collapse, accompanied with unconsciousness, and weakness or nervousness lasting several hours, coming at the finish of the relay race or a 440 yard trial, is likewise an undesirable condition in boys; insomnia, inability to study and continued loss of weight, in the absence of organic disease, are also unpleasant symptoms; yet each of these has more than once been found in the course of a not very extensive experience of examining school boy athletes. These conditions are not necessarily of a merely temporary character, for some of them have been under observation for from one to three years and have improved but little.

The sports in which danger most easily develops are football, basket ball, rowing and the track events of the mile run, the half-mile run and the relay race. Baseball, with the exception of the pitcher's position, is not very exhausting, and the short sprints, the hurdles, the jumps, the field events of the hammer and shot and the pole vault are not of a definitely continued exhausting character. Hare and hounds, or cross country running, is on the border line.

The following precautions suggest themselves: A preliminary physical examination, in which not only the heart, but the general condition, the growth and previous health should be considered; second, an increase of class competition in the same school and a diminution of interschool contests; third, shorter hours of organized practice and the establishment of a rule that none but the most physically competent be allowed to represent the school in more than one branch of sport, and that no one represent it in more than two branches; and, finally, a closer and more reasonable interest by the parents in the boy's physical exercise.

The interscholastic rowing which takes place in the spring on the Charles River, under the auspices of the Boston Athletic Association, is free from many of the objections described above; and the interest which it excites in the contestants, has not been diminished by the physical examination and its resultant exclusion of an occasional boy, or by the careful and limited methods of practice.

This article is not intended to suggest in any way a movement to diminish the amount or the number of the schoolboy sports. The writer is an ardent supporter of them in almost every form. In spite of press notoriety and the disadvantages above discussed, such sports are too valuable to be curtailed. They should, however, be supervised, so that their greatest good may be obtained and their obvious dangers, so far as may be, eliminated. This can be easily accomplished by making the sports a part of each school's curriculum, and by having one or more of the masters in close touch with the various teams.

THE REPORT OF THE STATE BOARD OF HEALTH OF MASSACHUSETTS.

THE thirty-fourth annual report of the board for the year ending Sept. 30, 1902, presents 649 pages of the high standard of excellence that we expect from year to year.

The death rates for the year and for the previous year, 16.17 and 15.82 per 1,000 living, are the lowest ever recorded in the state, and, in the absence of statistics as to the corresponding birth rates, are explained by the decreased death rate from infectious diseases, including pneumonia and tuberculosis, which destroy mainly the young and middle-aged. From diseases of the heart, brain and kidneys and from cancer the mortality is increased of late years, being in great part of older people who have passed the useful period of life. From these facts the board makes most interesting comparisons of the death rates of cities, which, although largely influenced by birth rates, depend upon the comparative preponderance of the young or the old in their communities.

The reduction of the death rate from "consumption" from 4.27 in 1853 to 1.59 per 1,000 in 1902, even if in part due to improved registration and diagnosis, means enormously improved sanitation; and the very low typhoid rate, 0.183 per 1,000, has the same significance.

The sanitary legislation for the winter of 1902-1903 records material advances in requiring from the towns monthly instead of yearly reports of vital statistics, thus securing much greater accuracy — relative to the destruction by boards of health of infected material; requiring an investigation and report on garbage and refuse dumped into sea or tide water; in regard to the sale of renovated butter; on separate systems of drainage, inspection of food and drug laws; relative to production and distribution of antitoxin and vaccine lymph.

A new office of the board has been created to collect information with regard to matters of public health, to investigate epidemics and high death rates and to bring the board into closer relations with local boards. Dr. F. L. Morse has filled the position to the great advantage of sanitation.

As usual, the greater part of the report (450 pages) is given to the discussion of the large questions affecting water, water supplies, sewerage and disposal of sewage and refuse, and to the advice given in individual cases by the board to cities and towns and corporations on these vital questions. On these matters the reports of the board have become the first authority both in this country and in Europe, and are of the utmost practical value.

There were examined during the year, by the board's officers, 6,256 samples of milk, 3,090 of other food than milk and 1,124 of drugs — in all 10,470, of which 2,989, or 28.1%, were found not to conform to the legal standard; and there were 76 prosecutions with 74 convictions. A list of 61 tonics and bitters is given, in which from 6 to 47.5% of alcohol was found.

In the eight years of that work, the board has manufactured and distributed 181,174 bottles of diphtheria antitoxin. Their records show a fatality of only 6.7% of cases treated during the first two days of the disease, 9 for the third

day, 12.9 for the fourth, 15.9 for the fifth and 17.6 for the sixth and later.

There were 928 specimens of sputum and other material examined during the year for the bacilli of tuberculosis; 217 of blood, for typhoid fever, of which 65 were positive; and 61 for malaria, in 17% of which the malaria parasite was found.

The statistical summary of disease and mortality, the usual comments on the health of towns and an admirable index complete the report.

The confidence of the community in the board and its high valuation of the work done are indicated by the generous appropriations of the legislature, for the year 1902, of $23,000 for general expenses of the board; of $11,500 for inspection of food and drugs; of $34,000 for the protection of the purity of inland waters; and of $2,500 for the examination of sewer outlets.

ANOTHER ORGANISM IN CARCINOMA.

IN a recent number of the *British Medical Journal* Mr. Keith W. Monsarrat, surgeon of the Northern Hospital at Liverpool, describes the morphology of an organism which he has found in carcinoma of the breast. This organism was described by him in 1899. Since that time researches have been continued with special reference to breast carcinoma, and out of the material which has been accumulated in that time he has been able to construct the life history of the previously described organism, and to adduce evidence which he regards of importance relative to its pathological relationship to the disease. Special care was taken in the removal and preparation of the material, and examinations were made at early periods after removal. From twelve specimens he was able to isolate the organism in seven. From observations made on this material, he reaches the following conclusions:

(1) From a considerable proportion (58.3%) of specimens of carcinoma mammæ, an organism presenting characteristic features was isolated.

(2) This organism presents a life-history in which two cycles were traced — the one a vegetative budding cycle, the other a sporulating cycle.

(3) The organism when injected into animals is capable of infecting and inhabiting endothelial and epithelial cells.

(4) The organism initiates in endothelium and epithelium a process of proliferation as a result of which masses of new-formed tissue are built up which consist of a parenchyma and a stroma, and grow and extend actively from their centers of origin.

(5) This new cell-mass formation may be associated with growth of a similar character in neighboring glands, and some evidence was also provided that visceral metastasis occurs.

(6) Intracellular bodies are demonstrable in carcinomata mammæ, which present the same features as the intracellular parasites of the experimentally produced nodules.

(7) The evidence derived from these researches points to the conclusion that the organism described is an etiological factor in the morbid process known as carcinoma mammæ.

We have no means of estimating the value of these observations. We quote them simply as another possible addition to our knowledge of the subject of etiology of cancer. It has apparently been easy to find various organisms in cancer nodules, and to trace certain changes in form. The all-important question of etiological significance, however, must remain unanswered until absolutely convincing experiments substantiate the findings of the microscope. In spite of vigorous and varied investigations this has not yet been forthcoming.

TESTING OF CLINICAL THERMOMETERS.

BY act of Congress in 1901 a Bureau of Standards was authorized, which among other duties was called upon to test clinical thermometers used in medicine. In order to approach the work with accuracy it was necessary to make a preliminary study of the magnitude and character of the defects in ordinary types of thermometers. To this end large numbers were studied relative to magnitude of errors, destructibility of index, time of action, effect of aging, nature of the glass, etc. It was forthwith established that there was a great lack of uniformity in standard among thermometers commonly used in this country. In general it was shown that the scale of thermometers was ordinarily about .2° F. too high, and a further study of the standards used by manufacturers of thermometers led to a verification of the conclusions previously reached. The manufacturers coöperated willingly in the work undertaken, with a result that the degree of error is now very much less, and a "uniform scale of thermometers" has been established.

Owing to the fact that manufacturers have desired to submit thermometers in large numbers for certification, rapid and accurate methods of testing have been devised. First, defects of construction, defective glass, air bubbles in the bulb, destructibility of index and certain other

matters are investigated, and if the thermometer is shown to be defective in any of these respects, it is refused certification. If the error in registration exceeds .3° F., such a thermometer is likewise refused. An important matter also, which is perhaps not sufficiently recognized, is the change which occurs with time. The greater part of such change takes place the first six months after the making of the thermometer, and the element of chief importance in this change is the chemical composition of the glass. If glass of recognized quality is used, the possibility of changes after six months may, from a practical point of view, be neglected.

The importance of this work needs only to be mentioned to be recognized. It is eminently desirable that an instrument so commonly used, and upon which so much often depends in the determination of the course of disease, should be as accurate as it is possible to make it. The work of the government in this respect, both directly and indirectly, has already proved of the greatest value.

MEDICAL NOTES.

MERGING OF TWO MEDICAL JOURNALS. — It is announced by the publishers of the *International Medical Magazine* and the *Archives of Pediatrics* that these two journals will be merged into a single periodical, retaining the title *Archives of Pediatrics*.

QUADRENNIAL CONGRESS OF POLISH PHYSICIANS AND SCIENTISTS. — The tenth quadrennial congress of the Polish physicians and scientists will be held this year in Lemberg, Austria, July 20–24. Prof. E. Machek is the Chairman of the Committee of Arrangements and Prof. W. Sieradzki, Secretary. Dr. Francis E. Fronczak of Buffalo, N. Y., is the representative of the committee for the United States.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, Feb. 10, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 49, scarlatina 38, typhoid fever 6, measles 149, smallpox 0.

A CENTENARIAN. — Mrs. Lavinia H. Crosby of Arlington, Mass., died Feb. 1, at the reputed age of one hundred and one years. She was born in Brewster, Cape Cod, and had lived for sixty-seven years in the house in which she died.

THE NEWTON, MASS., HOSPITAL. — At the annual meeting of the corporation of the Newton Hospital action was taken which practically removes from office the superintendent of the institution. The house officer will hereafter in a measure fill this vacancy. During the past year upwards of 800 patients were treated with some increase in expense over the year 1902. A new ward for maternity cases is needed.

FREE DENTISTRY. — A committee appointed last year by the trustees of Tufts College to visit the Tufts Dental School report, as a result of their investigation, that free dentistry is much needed in the city. The committee urges that approximately $4,000 a year would permit the free treatment of 8,000 more patients than are at present treated, and that such free treatment would be of benefit not only to a large number of individuals in the community, but also to dental students in the prosecution of their studies.

CRIPPLED AND DEFORMED CHILDREN IN MASSACHUSETTS. — According to a recent report of the state Board of Charity, inquiring into the number of crippled and deformed children in this state, who because of their deformity are unable to attend the public schools, it appears that 251 towns had no children of this class, that 65 towns reported 208 and that 36 made no reply to the inquiry. It is estimated that if a more rigid investigation were made, the entire number of children would amount to upwards of 250.

NEW YORK.

AT the annual meeting of the New York Graduates' Society of McGill University, held Jan. 27, Dr. J. A. Meek was elected President and Drs. H. N. Vineberg and William Ferguson respectively first and second Vice-Presidents.

BEQUESTS. — Among the bequests to charitable and religious institutions, aggregating $80,000, in the will of the late Mrs. Elizabeth W. Aldrich of New York, are the following: $10,000 each to St. Luke's Hospital and the Home for Incurables, and $2,500 to St. Mary's Free Hospital for Children.

DECREASE IN STREET ACCIDENTS. — The president of the Board of Police reports a gratifying decrease in the number of street accidents during the month, as compared with January, 1903, the figures being 159 and 213 respectively. There were 19 persons struck by cars, as against 39 in January of last year.

A Gift for Newark City Hospital. — The mayor of Newark, N. J., has received for the City Hospital a gift of $24,000, from the estate of Joseph Nichols, who died twenty years ago. Joseph O. Nichols, the cousin of the deceased, was appointed administrator, and after the various bequests in the will had been complied with, $11,000, which remained, was placed in savings institutions, where, with the accumulations by interest, the amount has increased to $24,000.

"Liquid Sunshine." — At the annual dinner on Feb. 5 of the Technology Club, which is composed of New York alumni of the Massachusetts Institute of Technology, "liquid sunshine," prepared under the direction of Dr. William J. Morton, was one of the beverages provided. Each guest had a glass of water containing a small quantity of esculin, and into this he dropped a capsule which had been rendered radio-active by exposure to radium. After drinking the liquid none of the diners appeared to become translucent, but they were assured that their interiors were thoroughly illuminated.

Orthopedic Dispensary and Hospital. — At the annual meeting of the Board of Trustees of the New York Orthopedic Dispensary and Hospital, which was held on Jan. 25, it was announced that Miss Emily A. Watson, one of the supervisory board of the institution, who had previously given $100,000 for the erection of a country branch, has now presented an endowment fund of $250,000 for the maintenance of the same. This new building, which is approaching completion, is a substantial structure three stories in height, located at White Plains, Westchester County, and is surrounded by fifteen acres of land. It is designed as a convalescent hospital and industrial school.

Inspection of Schools. — At a meeting of the Board of Education held Feb. 3, Health Commissioner Darlington recommended the temporary closing of one public school and the disuse of certain class-rooms in two other schools in the Borough of Brooklyn. Dr. Darlington also urged improvement in the sanitary conditions in nine other schools in Brooklyn. These recommendations were based on the results of an investigation made by Dr. Charles F. Roberts, sanitary superintendent of the Health Department. The school, the closing of which was advised, is an old one-story frame structure, which was found to be insufficiently heated, while the arrangement of the class-rooms is bad and the plumbing defective.

Mount Sinai Hospital. — The annual meeting of the directors of the Mount Sinai Hospital, the last at the old buildings, was held on Jan. 24. It was announced that the new hospital, at Fifth and Madison Avenues, between 100 and 101st Streets, will probably be opened the middle of March. On Dec. 1, 1903, the entire subscriptions to the building fund aggregated $1,435,568, of which $152,139 was received during the past year. The following figures show the relative size of the old and new buildings: Total number of beds in the present hospital, 225; total number of beds in the new hospital, 456. Cost of maintenance of the present hospital and dispensary, annually, $144,319; estimated cost of maintenance of the new institution, annually, $250,000.

Hebrew Infant Asylum. — The ninth annual meeting of the Hebrew Infant Asylum was held on Jan. 27, when the annual report showed that during the past year the mortality among the inmates, ranging from newborn infants to children five years old, was less than 2½%, as compared with a general outside rate for children between those ages of 10%. Of the 248 children cared for during the year, only 6 died. The president of the institution announced that toward the fund being raised for the erection of a new building, to accommodate 500 children, $40,000 of the $175,000 required had now been subscribed. The asylum is at present located in the eastern section of the Borough of the Bronx, but it is purposed to have the new building on the western side of the Bronx, and negotiations are now in progress for the purchase of a desirable site.

Clean Bank Notes. — On Jan. 29, in Washington, Dr. Darlington, President of the New York Board of Health, was heard by the Banking and Currency Committee of the House of Representatives on the pending bill providing for the issue of new notes to the end that the paper currency may be maintained in good sanitary condition. He expressed the opinion that a provision for keeping this as clean as possible by constant renewal would be a step in the right direction. He also believed that a plan could be arranged by which the money (coins as well as bills) received by the street car companies, large retail stores, etc., of the principal cities might be sterilized each day or each week. At present, he said, an investigation was being made in the New York Health

Department laboratories, to determine, as far as this was possible, to what extent disease germs are transmitted by means of money.

MORTALITY IN JANUARY. — The Health Department reports show that during the month of January the mortality in the city represented an annual death rate of 21.22, as against 18.53 in December and 19.32 in January, 1903. The corrected death rate, excluding non-residents and infants under one week old, was 20.32. Among the diseases in which there was an augmented mortality were the following: The weekly average of deaths from diphtheria and croup increased from 47.25 in December to 51 in January; the weekly average from scarlet fever, from 17.75 to 28; from measles, from 9 to 19.25; from influenza, from 8 to 15; from pneumonia, from 186.75 to 226.5; from broncho-pneumonia, from 88.25 to 122.25; from acute bronchitis, from 37.5 to 56; from diarrheal diseases, from 34.5 to 36.25; from diarrhea under two years of age, from 25 to 28; from cancer, from 52.75 to 56.5; from Bright's disease and nephritis, from 114.75 to 137.25; and from organic heart diseases, from 97.5 to 108.25. Among the diseases in which there was a decreased mortality were the following: The weekly average of deaths from whooping-cough declined from 3.75 to 1.5; from typhoid fever, from 13 to 7.5; and from pulmonary tuberculosis, from 162 to 157.75. During the month there were two deaths from smallpox; with the exception of one other, in the early part of December, these are the only deaths reported from this disease for many months.

EXTERMINATION OF MOSQUITOES. — The Park Department, which for some time has been engaged in cleansing the lakes and pools of Central Park, announces that it has got rid of mosquitoes in that resort. Incidentally the investigating committee, consisting of Dr. E. B. Southwick, city entomologist, and Dr. William N. Berkeley, of the Board of Health, has reported that, despite assertions to the contrary made by physicians and others, there never were many mosquitoes of the anopheles variety in the Park.

ST. BARTHOLOMEW'S CLINIC. — The Year Book of St. Bartholomew's parish, just issued, has the added interest of being the last to appear during the remarkable rectorate of Dr. David Greer, who has now been made bishop coadjutor of New York. When Dr. Greer took charge fifteen years ago, there was but one feeble little benevolent society; but the religious and benevolent work of the parish has now developed into enormous proportions, and during the past year, at the St. Bartholomew Clinic, fifty physicians and surgeons have given free service to more than 13,000 patients.

Miscellany.

THE BUMMER AND THE GUMMA.

BY G. L. WALTON, M.D., BOSTON.

THE following jingle has served to fix the pathology of central nervous syphilis in the mind of the writer. It is forwarded in the hope that it may serve the same purpose for others equally dependent on kindergarten methods.

The gay and festive bummer, when he goes upon a bum,
Inaugurates proceedings with a bottle full of rum.
This serves the vessels to dilate, resistance to impair
Of tissues of the cerebrum, and thus prevents repair,
Facilitating movements of that wicked little bug,
Which does not hit you on the head like ordinary thug,
But finds its way, without delay, to regions most remote.
(On this authorities agree, too numerous to quote.)

He first attacks the arteries, upon their inner layer,
And when he's caused an exudate, it's apt to be a stayer;
It blocks the passage of the blood, and favors a thrombosis,
Not subject to relief by en-, or even ex-, osmosis.
The adventitia swells a bit; profuse proliferation
Of cunning little rounded cells increases the stagnation.
A little fibrous tissue, and a cheesy breaking down,
Will serve to make a gumma; — for the man who's seen the town.

Its surface is irregular, the cheesing is in spots,
Surrounded by a granuled mass of microscopic dots.
Sometimes the vessel wall is most as jagged as Formosa;
Pathologists call this effect "arteritis gummatosa."
More commonly this growth is found in membranes of the brain,
Or in the substance of a gyre, or in the pons again,
More rarely in the capsule, but quite often at the crus,
Crossed palsy being thus produced with very little fuss.

Sometimes the process is diffuse; a gummous exudate
Spreads round the vessels of the base, not coming quite so late
As gumma, which you sometimes find twelve years or more delayed
Beyond the time the patient states infection was conveyed.
A year will make a gumma, though, says Strümpell in his treatise,
Three months sufficing to produce effective meningitis.

This plays about the cranial nerves, whose endo-
neurium
Swells up in spots unduly prone to pinch the fibers
some!

A gummatous neuritis is the name they give this
stunt,
Of which the nervous fibrils have, alas, to bear the
brunt.
A serous imbibition forms the next important issue,
Which may produce an atrophy, with cicatricial
tissue.
Gelatinous material in diffusive neoplasm
Is fond, as Oppenheim has said, of squeezing the
chiasm.
So don't forget to take the fields, 'twill help you out a
bit,
In case you lack paralysis, strabismus, or a fit.

These lesions dire, like forest fire, are very hard to
smother,
To-day appearing in one place, to-morrow in another;
That's why the learned Oppenheim and Peterson, also,
Say "Syph of central nervous Syst," and let the old
plan go,
Of "Syph of cord" or "Syph of brain";—the awk-
wardness was great
Of naming from the part worst hit, by gummous
exudate.
(This exudate is rather prone small lesions to produce,
So never look to find that form of *neuritis* called
diffuse.)

Diffuse and circumscribed attack may join in doing
harm,—
There may be palsy of an eye, the face, or leg, or arm;
A gumma, arteritis and neuritis may consort;
So don't be rash in forecasting the pathologist's
report!
When meningitis gets well set, it makes a stiff mem-
brane,
To start which you use iodide again and yet again.
And don't forget the softening, which leaves the brain
forlorn,
In parts from which, through syphilis, the circulation's
gone.

A lobe, or a whole hemisphere, has been known thus
to fall,
Producing hemiplegia; not to mention death at all.
Above all, just remember that the symptoms come and
go,
And change almost from day to day, with gummous
ebb and flow.
Remember that the iodide, in any doubtful case,
May serve at least for rheumatiz, and maybe lead
displace.
Recall G. P., and tabes too, from toxines of the gumma
Which any time may overtake this gay and festive
bummer.

THE MEDICAL EXAMINING BOARD OF SOUTH CAROLINA.

THE medical bill which is now before the legislature of South Carolina, as regards sections which deal with examinations of students by the state board, is drawn entirely from an article entitled, "The True Function of the State Examining Board," prepared and read by Dr. Allard Memminger, four years ago at a meeting of the South Carolina Medical Association and published in this JOURNAL July 26, 1900. Had the ideas contained therein been then adopted it would have probably avoided all the trouble which the exemption clause passed in the students' bill two years ago has caused.

The present bill exempts no one, but provides fully and fairly for the students who graduate at a four-year graded school, and who attain 75% on all of the junior branches. On these they are, by the provisions of this bill, freed from coming before the state board, and these junior branches of the curriculum include general anatomy; physics; chemistry, organic and inorganic; physiology; materia medica and medical botany; bacteriology; histology and pathology.

They thus, after receiving their diplomas, are only examined by the state board on the practical branches of their curriculum, to which they have, of course, devoted all their study during the latter portion of their medical term.

WE must again ask the indulgence of our readers for the delay in the issue of the JOURNAL, which has been caused by a continued strike of printers and pressmen.

Correspondence.

IMPOSTOR.

BOSTON, Feb. 8, 1904.

MR. EDITOR: Some time ago I called attention in the JOURNAL to a man who then gave the name of Dr. —— Allen of New Orleans, who was soliciting money either by gift or loan (?) from the members of our profession, on the pretence that he had been robbed. This man is again among us, and has already called on some of his former dupes. Will you kindly again warn the profession against this *impostor*, who has a public record for fraud, and thus perhaps benefit some of our associates?

Sincerely yours,
ALBERT N. BLODGETT, M.D.

MORPHINE AND MENSTRUATION.

BALTIMORE, MD., Feb. 2, 1904.

MR. EDITOR: Your excellent editorial, "The Menstrual Functions of the Morphine Habitué," in the JOURNAL of Jan. 30, contained statements of conditions too little regarded or understood by the average physician. To those who have an intimate acquaintance with morphine victims the reason is obvious.

I have found many women in social life and the theatrical profession, as well as in the *quatre monde* of Paris and Vienna, who commenced the use of morphine with the sole purpose of preventing pregnancy. Only a short time ago a woman of twenty-eight years of age was sent to me for treatment who was using 40 or 50 gr. of morphine a day. This patient informed me that she had been told by a schoolmate that a grain at bedtime and another one in the morning would prevent pregnancy. Several years ago I learned from women on the Continent that they all considered morphine a certain preventive, and, as can be readily understood, when used for a few weeks this remedy is not apt to be neglected.

Truly yours,
WILLIAM LEE HOWARD, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JAN. 30, 1904.

CITIES.	Population Estimated, 1904.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Acute lung diseases.	Diphtheria and croup.	Diarrheal Diseases.	Typhoid fever.

Deaths reported, 3,774; under five years of age, 1,061; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 752, acute lung diseases 865, consumption 375, scarlet fever 49, whooping cough 9, cerebrospinal meningitis 14, smallpox 18, erysipelas 18, puerperal fever 9, measles 35, typhoid fever 45, diarrheal diseases 80, diphtheria and croup 87.

From whooping cough, New York 1, Philadelphia 3, Baltimore 1, Pittsburg 2, Boston 2. From smallpox, Chicago 1, Philadelphia 17. From cerebrospinal meningitis, New York 6, Baltimore 1, Providence 1, Boston 2, Worcester 4. From erysipelas, New York 5, Chicago 4, Philadelpha 3, Pittsburg 1, Providence 1, Boston 2, Taunton 1, Marlborough 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,425, for the week ending Jan. 16, the death-rate was 19.0. Deaths reported, 5,557; acute diseases of the respiratory organs (London) 217, whooping cough 131, diphtheria 51, measles 136, smallpox 2, scarlet fever 44.

The death-rate ranged from 8.5 in Coventry, to 38.2 in Wigan; London 18.8, West Ham 19.9, Brighton 15.3, Southampton 20.4, Plymouth 22.9, Bristol 16.6, Birmingham 21.7, Leicester 15.1, Nottingham 17.8, Liverpool 23.1, Bolton 21.1, Manchester 18.9, Salford 20.7, Bradford 20.7, Leeds 21.4, Hull 15.2, Cardiff 18.0, Rhondda 22.2, Marthyr Tydfil 33.0, Barrow-in-Furnace 19.2, Preston 29.0.

METEOROLOGICAL RECORD.

For the week ending Jan. 30, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

RECENT DEATHS.

DR. JOSEPH G. ROONEY of West Hoboken, N. J., died on Feb. 4 in St. Mary's Hospital, Hoboken. His death was the result of exposure in intensely cold weather on the night of Jan. 18, when he nobly attended a number of firemen who had been injured at a fire in Jersey City Heights. His hands were badly frostbitten, and subsequently gangrene set in, the progress of which it was found impossible to stop. Dr. Rooney was a member of an old West New York family, and was formerly town physician of that place.

JOSEPH B. ROE, M.D., of Woodbury, N. J., died on Feb. 5, at the age of sixty-eight years. During the Civil War he served as a surgeon in the army, and from 1888 to 1890 was a member of the New Jersey State senate. During his term of service in the legislature he was a member of the special committee appointed by the State senate to inquire into the Hudson County ballot box frauds, and was instrumental in producing before the committee the testimony upon which sixty-four of the election officers were afterwards sent to State prison.

SOCIETY NOTICES.

NEW ENGLAND HOSPITAL MEDICAL SOCIETY.—The regular meeting of the New England Hospital Medical Society will be held at Hotel Nottingham Feb. 18, 1904, at 7.30 P.M. Scientific program under charge Section on Nose and Throat. Dr. Alice G. Bryant, Chairman. Paper by Dr. Emma E. Musson of Philadelphia, entitled "Some Recent Experiences with Acute Nasal Sinusitis."

MARION NUTE, M.D., Secretary *pro tem.*
32 Mill St., Dorchester.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—The regular meeting of the society will be held in Sprague Hall, Medical Library, on Monday, Feb. 15, at 8.15 o'clock. Dr. H. C. Ernst will speak on the "Means by Which Tuberculosis Spreads." "Should the Medical Profession of Boston Urge the Establishment of a Municipal Hospital for Tuberculous Patients?" Dr. Knight, Dr. Otis, Dr. Howard, Dr. Rowe, Dr. Bowditch, Dr. Minot, Dr. Stone, Dr. Cox, Dr. Markley, Dr. Allen and others will take part in the discussion.

CHARLES M. GREEN, M.D., President.
ARTHUR K. STONE, M.D., Secretary.
All interested are invited to attend.

LECTURES ON TUBERCULOSIS: THE HENRY PHIPPS INSTITUTE.—The next lecture in the international course on tuberculosis, under the auspices of The Henry Phipps Institute, will be given by Dr. Herman M. Biggs, Chief of the Department of Health in New York, on Monday evening, Feb. 15, the subject being "The Administrative Control of Tuberculosis." The profession in general is cordially invited to attend this lecture.

APPOINTMENTS TO THE STAFF OF THE BOSTON DISPENSARY.

Physicians, Dr. F. W. Stuart, Dr. Percy Musgrave. Gynecologists: Surgeon, Dr. Edgar Garceau; Assistant Surgeons, Dr. F. X. Crawford, Dr. Herbert S. Gay. Throat Department: Surgeon, Dr. H. P. Mosher. Rectal Department: Surgeon, Dr. James H. Grimes. Nervous Department: Assistant Physician, Dr. F. B. Granger. Men's Massage Department: Mr. E. H. Harding.

Original Articles.

SLIPPING OR RECURRENT DISLOCATION OF THE PATELLA. WITH THE REPORT OF ELEVEN CASES.

BY JOEL E. GOLDTHWAIT, M.D., BOSTON.

THE above condition is seen almost entirely in girls or women, and is due, in large part, to the fact that the line of pull of the quadriceps extensor muscle is not straight, this feature being increased in its effect by an unnaturally long patella tendon, knock knee or an imperfectly developed articular surface at the end of the femur. Eleven cases of this condition, seven operative with thirteen operations, and four non-operative, have been seen and treated by the writer, and the observations made in connection with the treatment of these cases represents the basis of this paper.

The first feature, or the indirect muscle pull, is in part normal anatomically. The tubercle of the tibia with the attachment of the patella tendon is distinctly to the outside of the central portion of the patella when the knee is extended and the muscles are at rest. As the action of the muscles, together with the joint motion, is studied, it is seen that during flexion the patella is drawn forward over the articular surface between the condyles of the femur and inclines slightly but distinctly to the outside of the median line. As extension takes place the patella ascends, inclining slightly toward the inner side until, when extension is complete, the line formed by the origin of the rectus femoris, the center of the patella, and the tubercle of the tibia makes an obtuse angle (Fig. 1). As the muscle contracts the natural tendency is to straighten this line, with the necessary result that the patella is drawn outward, representing, as it does, the only movable point in the line. This can easily be demonstrated in any normal joint if the knee be fully extended and the quadriceps muscle be alternately contracted and relaxed. The lateral movement of the patella is distinct, the limit outwardly being controlled in part by the ligaments, but more particularly by the outer ridge of the trochlear surface of the femur, which is distinctly higher in its upper and anterior surface than the same ridge at the inner side (Fig. 2). Against this the patella impinges, and displacement further is impossible as long as all the parts are normal.

FIG. 1 (Gray).

FIG. 2 (Gray).

If for any reason the line of pull becomes less direct or the articular ridge less perfectly formed; if the capsule be weakened by the distention following some acute injury; if the patella tendon be abnormally long so that the patella is drawn above the outer edge of the trochlear surface of the femur; or if the joint can be hyperextended so that during the muscular pull the patella is lifted away from the femur — in any one of these conditions the stability of the joint, so far as the patella is concerned, must be materially lessened.

The displacement of the patella, which results from such a mechanical condition, may occur frequently with simple motion or muscular contraction, or may develop only when attended with the application of considerable force and when combined with some lateral strain, the ease or difficulty of the displacement depending, of course, upon the degree to which the normal condition has been modified. In the extreme conditions the displacement may become permanent, in which case the inner portion of the capsule becomes permanently stretched while the outer portion shortens. In this condition the patella rests upon the outer surface of the outer condyle of the femur, and complete extension,

which depends upon the pull of the quadriceps extensor, acting through the patella over the lower and anterior surface of the femur, is impossible. If this extreme or permanent condition occur in childhood or before the bone growth is complete, the condyles of the femur conform in their development to the range of motion, so that ultimately complete extension of the joint is impossible, the limitation not being due to ligamentous or tendonous contracture, but to a change in the articular planes. These extreme features were present in Case I.

It is also true that if the displacement persist for any length of time in the growing child a twist in the upper end of the tibia results, so that even though the patella be replaced the angle in the pull of the muscle is so much increased that displacement occurs as soon as the muscle contracts.

From my observations in this limited number of cases it seems to be true that if the patella has slipped out several times without special violence it is an evidence of joint instability, due to one of the above-mentioned conditions; and while the slipping may be controlled by simple measures, the weakness usually remains and the joint is unable to stand the strain of normal use. For this reason, although bandaging, braces for the knees, the correction of flat or pronated feet, should always be tried in the early stages of the trouble before the slipping has become frequent, comparatively little is to be expected in the way of permanency of relief from such measures, if the slipping has recurred several times, unless the patient be very young.

The chief point in the treatment naturally consists in the correction of the angle in the line of muscle pull so far as it is possible. If knock knee be present, the lateral motion of the patella during use will naturally be increased. If the knock knee is due simply to the loose internal lateral ligaments, it is conceivable that by thoroughly correcting this the lateral movement of the patella may be lessened and the slipping or dislocation cease. I have not been able to accomplish this in any one of the cases here reported, although one seemed favorable as to age; but to expect improvement is reasonable from the study of the mechanics, if the cases can be seen before bone or other permanent changes have taken place.

If marked knock knee with the usual bone changes be present, this should, of course, be corrected, but as this feature was present in but one of the cases under discussion it is probably not as common as has been supposed.

If the patella tendon be long, so that in complete extension the patella is drawn above the outer ridge on the trochlear surface of the femur, it should naturally be shortened, as unless the normal mechanical relations can be restored the joint must be unstable. To correct this the tendon should be shortened, and in doing this it is better, as it lessens the danger of relapse, at the same time to change the attachment of a portion of the tendon, thus making the line of pull more nearly straight. In the one case in which the tendon was simply shortened relapse occurred, entire relief following the second operation, in which the other half of the tendon was transplanted.

If after studying the mechanics of the given joint carefully the relaxed inner half of the capsule is the only defect, this should naturally be tightened. It is my impression, however, that this is almost never the case, and that the relaxed capsule is a result of an abnormal condition rather than the cause, and that if the cause be corrected the relaxation of the capsule will take care of itself. In the three operations performed by me in which only the inner portion of the capsule was tightened all relapsed, while in the cases which have been operated on since and the patella tendon reattached the capsular relaxation has entirely disappeared, although at the time of the operation the capsule itself was entirely ignored.

In the majority of the cases, when carefully studied, it will be seen that the attachment of the patella tendon is distinctly farther to the outside than normal, making less direct the pull of the anterior thigh muscles, and with this the ridge on the outer edge of the articular surface of the femur is less marked than normal.

The treatment which has been most satisfactory in meeting this condition is an operation in which the outer half of the patella tendon is reattached to the tibia, well to the inside of the tubercle. In this way the angle in the muscle pull is lessened or entirely removed, so that the patella is drawn firmly across the articular end of the femur and the presence of the ridge at the outer side is made of less importance. Of the eight operations which have been performed in which this has been the chief feature, in seven no after trouble has resulted, and the stability of the joints has made them equal to normal use. In one in which the tendon had, at the same time, been shortened, the first attachment did not remain firm, so that a second operation was necessary.

The operation as carried out at present consists of a longitudinal incision four or five inches long, extending from just below the tubercle of the tibia upwards. Through this the patella tendon is exposed and split in halves, anteroposteriorly, throughout its entire length. The outer half is then cut from its attachment, passed under the remaining portion and attached to the periosteum together with the expansion of the tendon of the Sartorius muscle at the inner side of the anterior surface of the tibia (Fig. 3). If it is desirable to shorten the patella tendon the attachment can be so made that the patella is drawn down as much as is desirable, but as this means much tension upon the new attachment a hole should be drilled in the bone at the point of attachment, through which the suture is passed which holds the tendon. The carrying of the free portion under the other is of importance, as in this way the patella is tilted, the outer portion being drawn downwards, and

impinges more firmly against the outer ridge of the articular surface of the femur during muscular contraction so that the danger of displacement is materially lessened.

The attachment is made with strong silk, quilted through the tendon; the wound should be tightly closed, and the leg fixed in a plaster of Paris bandage from the ankle to the groin, the contraction of the quadriceps extensor being eliminated as much as possible by applying a tight gauze bandage from the knee to the groin under the plaster. The fixation should be kept up for about six weeks.

In performing the operation the inner half of the tendon, or that most favorably situated for the direct muscular pull, is entirely undisturbed, so that in case the transplanted portion fails to unite function is still possible, and some improvement must still result, as the simple removal of the outer half of the tendon practically moves the existing attachment of the tendon that much farther to the inside.

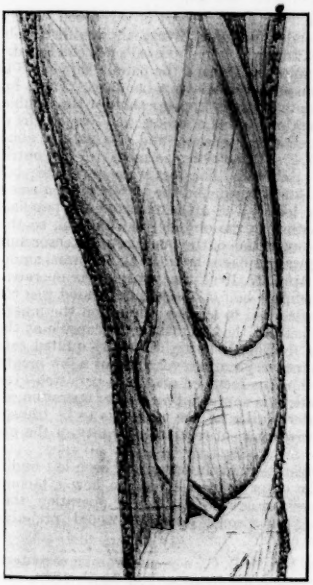

Fig. 3.

In perfecting the operation various measures have been tried. The inner half of the tendon in one case was transplanted with ultimate relapse; the entire tendon was transplanted in one case with a perfect result, but this was not repeated, as the later operation possessed less danger from possible failure of the new attachment to hold; in one case the patella tendons wa shortened with subsequent relapse; and in ona case the entire tubercle of the tibia was transplanted and nailed to the inner side of the tibis with a good functional result, but with a much longer convalescence than is required in the operation described in detail above. The cases in which simply the inner portion of the capsule was shortened all relapsed.

The cases are reported in detail below. In the operated cases, with possibly one exception, a sufficient length of time has elapsed for a thorough test of the joint to have been given.

Case I. This case has been previously reported (Annals of Surgery, January, 1899) and represents a case of dislocation of both patellæ, in which the malposition had become permanent. The patient was a woman thirty years of age, and was first seen in February, 1895. The trouble with the knee began without injury at ten years of age. Treatment was sought because of pain in the back which resulted from the peculiar attitude in standing.

On examination both patellæ were on the outer surface of the outer femoral condyles, and replacement was impossible. The tibia was rotated outward considerably so that the attachment of the patella tendon was much farther to the outside than normal, and complete extension of the knee was impossible, due apparently to the abnormal development of the articular surfaces of the lower end of the femur. On standing, the knees were flexed and braced against each other, increasing considerably the normal lumbar curve, with resulting muscle strain and backache. There was slight knock knee, and the gait on walking was awkward, one leg being thrown around the other. Horizontal extension of the legs was impossible. The correction of the position of the patellæ by any manipulation was impossible, so that the patient entered the Carney Hospital, and in March, 1895, the right knee was operated upon as follows:

Through an eight-inch incision, beginning above the knee on the outside and extending downward across the knee to the inside, the capsule of the joint was exposed. Even with the skin removed the patella could not be brought up into its normal position, and a longitudinal incision three inches long was made through the outer part of the capsule. After this the dislocation could be corrected without difficulty, but because of the change which had taken place in the shape of the ends of the bones, the tubercle of the tibia was so much farther to the outside than normal that, when the joint was flexed, the patella slipped out of place again. In order to obviate this, and to have the attachment of the patella tendon in the proper place, the tendon was cut off and sewed to the periosteum and the expanded tendon of the Sartorius on the inner and anterior surface of the tibia. The loose capsule on the inner side of the joint was next shortened with quilted sutures, and for fear that the strong thigh muscles should tear away the new attachment before it should become firm, about three-fourths of the quadriceps extensor was divided just above the patella. The wound was then tightly closed, the skin being depended upon to close the gap (three-quarters of an inch broad) in the outer part of the joint capsule made necessary to draw the patella forward.

The recovery was uneventful, there was very little pain and practically no elevation of temperature. The wound was healed in one week, and motions, which were not in the least restricted, were allowed at the end of one month. A leather knee splint, to prevent any sudden violence and the possible tearing away of the newly attached tendon, was worn during a part of the time for a few months. As soon as the patient was able to be about, even though one patella

was in place and the action of the knee improved, the difficulty in completely extending the knee remained, so that the lordosis was not lessened. To correct this an osteotomy of the femur above the condyles was performed in both legs and the knees straightened. The convalescence from this operation was uneventful, and eight weeks from the time of its performance the left knee was operated upon to correct the position of the patella. The operation was similar to that which was used in the other joint, except that, instead of cutting off the patella tendon and re-attaching it, the whole tubercle of the tibia was chiselled off and nailed to a depression which was made on the inner side of the bone. The reason for this change in the procedure was that while the other knee had shown no signs of weakness, nevertheless, it was my feeling that a bony attachment would probably be more secure. With this, of course, it was not necessary to cut away so much of the attachment of the quadriceps extensor above the patella.

Instead of the primary union, as was obtained in the other knee, the tendon and the piece of transplanted bone sloughed considerably, so that, instead of healing in one week, about three months were necessary before the wound was entirely closed. During much of this period the patient was able to be about, but the healing was not complete until then. The functional result in this joint is also not as good as in the right, and, while complete extension is possible, there is only about 90% of motion in flexion.

Since the operation there has never been the slightest indication of the old pain in the back, the lordosis has been corrected, the gait is much improved and, except for the limitation in flexion in the left knee, the patient is perfectly well, with the normal function of the joints. On walking or standing the inward rotation of the legs has disappeared, and on sitting complete extension of the leg is easily performed entirely without the twist of the leg that developed with the attempt at such movement before the operation. It is now seven years since the last operation was performed, and during much of that time the patient has been at work in a factory able in every way to meet the demands made upon her.

CASE II. Miss M. L., thirty years of age, was seen in consultation with Dr. Charles P. Putnam, in April, 1897.

Since childhood both knees had slipped on slight provocation, the condition having come on without injury or other known cause. The slipping caused great inconvenience, producing frequent falls, and being followed commonly by joint swelling.

Bandages, massage and appliances had been thoroughly tried and failed. Accordingly both knees were operated upon, and the inner portion of the capsule of the joint was shortened so that when the wound was closed it was impossible to slip the patella out of the trochlear groove. At the time of this operation the importance of attachment of the patella tendon in its relation to the line of pull was not appreciated by me, and as there was no literature upon the subject, this feature was entirely ignored.

After the operation the wounds were tightly closed and the period of healing was uneventful. Very soon, however, after the patient began to go about the capsule stretched again so that the dislocation recurred, there being no permanent improvement from the operation.

Further operation was refused by the patient.

CASE III. Mary F., seventeen years of age, was seen May 29, 1897, because of slipping of the left patella, which had begun five or six years before without known injury, and had slipped at infrequent intervals ever since.

At the time of the first examination the chief feature to attract attention was the abnormal length of the patella tendon. The attachment of the tendon in this instance was not noted and the first operation consisted of shortening the tendon about three-fourths of an inch and quilting the inner side of the capsule of the joint. The healing after this operation was uneventful and the immediate effect was satisfactory, but later on, however, the slipping or dislocation recurred and became as troublesome as before.

As the essential principle of the treatment had been by this time recognized, a second operation was performed Jan. 18, 1901, and the outer half of the tendon was cut away, passed under the undivided portion and attached well to the inside of the tibial tubercle, as has been described above.

The recovery was uneventful, and no further trouble has resulted. The knee is used freely and is apparently perfectly strong.

CASE IV. E. R., a girl of seventeen years of age, came under treatment five years ago for trouble with the left knee which had existed since childhood. Under the simplest movement the patella slipped to the outside, unless controlled by a bandage. There had been no definite injury or known cause for the trouble. The examination showed a strong, well-formed girl with the left knee much relaxed and the patella abnormally movable, so that displacement to the outside was easily produced. The feet were quite flat, but there was no knock knee, and the patella tendon was not unusually long. The attachment of the patella tendon was farther to the outside than normal, so that with every contraction of the quadriceps extensor muscle the patella was displaced laterally an abnormal amount.

On April 27, 1889, the patient was operated upon, and the inner half of the patella tendon was cut away and reattached to the periosteum on the inner side of the tibia. At the same time the capsule at the inner side of the joint was tightened by quilted sutures.

The recovery was uneventful, but a few months later the symptoms recurred and have persisted ever since. The patient is now awaiting further operation, in which the outer portion of the tendon is to be transplanted, thus correcting entirely the obliquity of the muscular pull.

In this case had the inner half been left undisturbed and the outer portion given the new attachment, as has been the case with the later operation, the necessity of the second operation would probably have been avoided.

CASE V. M. C. C., a young woman seventeen years of age, came for treatment in April, 1899, complaining of trouble with both knees. When nine years of age she was thrown down and one patella slipped out. Soon after this the other slipped, and ever since at intervals varying from a few weeks to a year the slipping has been repeated, sometimes one and sometimes the other giving out. After each slipping the joint has swelled, necessitating quiet and bandaging for a few weeks. The slipping occurred sometimes with violent use and sometimes upon slight movement.

The examination showed a strong, well-formed girl, the only apparent defect being the relaxation and weakness of both knees. The patellæ could easily be displaced laterally, and their lateral movement to the outside, during the contraction of the quadriceps muscle, was quite noticeable. There was no knock knee, and but slight pronation of the feet.

Previous to consulting me the patient had had for over a year systematic massage with some mechanical

treatment, without improvement, so that after first correcting the pronation of the feet, still without improvement, an operation was performed, in which the outer half of the patella tendon was transplanted to the inner side of the tibia, as has been described above. Both knees were operated upon at the same time. The recovery was uneventful. At the end of four weeks the plaster bandages were removed and movement allowed in bed. Two weeks later the patient was allowed up, the only protection being a light flannel bandage, which was worn during the daytime for a few months.

As to the ultimate result, in the four years which have elapsed since the operation, the patient has been active in sports and games, with absolutely no weakness or symptoms referable to the knees, except that once in a romp she was thrown, wrenching one knee, causing a few days of discomfort. Even in this violence the stability of the joint was not disturbed.

It is an interesting fact that in this case, while the capsule had been much relaxed, and even though no attempt was made to tighten it at the time of the operation, the normal tonicity of the structures returned with the restoration of the normal mechanical function and the relief of the lateral strain.

Case VI. M. C., a young woman twenty-three years of age, was seen in 1895, and treated for marked flat foot. For several years before this the knees had been quite troublesome, slipping occasionally, sometimes one knee and sometimes the other. No definite cause could be assigned for the trouble.

The examination showed a strong, well-developed woman, with quite marked flat foot and with relaxed knee joints, but with no knock knee. The movement of the patella to the outside during the contraction of the anterior thigh muscles was quite apparent. Because of the definite character of the flat foot it was thought wise to correct this first, hoping that by lessening the strain upon the knees the weakness and slipping might be modified. This, however, did not result, but instead the weakness and slipping became more marked, so that while at first considerable violence was necessary in order to develop the trouble, gradually the displacement became more and more easy, until it was apt to follow any slight simple movement, naturally causing great limitation of activities.

In May, 1901, an operation was performed, and the outer half of the patella tendon was transplanted. Both knees were operated upon at the same time, and after six weeks in bed regular use began. Since then the patient has lived a thoroughly active life without the slightest evidence of weakness.

Case VII. C. G., a young girl seventeen years of age, was seen in June last at the Vincent Hospital, in consultation with Dr. Mary P. Hurd.

The history was that eight months before the left knee was sprained, at which time the patella was probably dislocated. Without special violence the patella distinctly slipped out two months ago, and since that time it has slipped frequently and with but slight movement. On even turning over in bed the dislocation often occurred.

The girl was of good height and of fairly good physical development. The left knee was much relaxed with but little increase in the synovial fluid, and the lateral movement of the patella was so free that with but very little force it could be entirely displaced. The patella tendon was fully a half inch longer than normal, and the articular ridge on the outer edge of the trochlear surface of the femur was much less distinct than usual. The angle in the line of pull of the quadriceps extensor muscle was quite distinct. There was slight knock knee, and the pronation of the feet was marked.

For treatment the pronation of the feet was corrected and the knee strapped with adhesive plaster, and over this a flannel bandage applied, but in spite of this the slipping continued, and, as only when the knee was fixed in a plaster of Paris bandage was the slipping controlled, an operation was advised.

In the early part of July the outer half of the patella tendon was attached to the inner side of the tibia, the only difference from the operation performed in the last two cases being that, as the patella tendon was too long, a lower attachment was made and the patella drawn down to its normal position. The undivided portion was not shortened, as it was considered that this would take place unaided with the relief of the strain, as is seen in other analogous conditions.

The result from this operation was disappointing. When use was first allowed there was no trouble, but very soon the slipping recurred, due apparently to the failure of the new attachment to hold. The slipping was naturally less marked than in the beginning, owing to the removal of the outer half of the tendon, but it was sufficient to cause considerable insecurity in use. To overcome this a second operation was performed and the tendon reattached, the suture being passed through a hole which was drilled in the bone at the point of attachment. The knock knee, even though not marked, was also corrected by osteotomy. The end result in this case cannot be stated, but as the faulty mechanical features have been corrected, it seems reasonable to expect a stable joint.

Case IX. N. M., a young woman twenty-three years of age, was first seen in April, 1899. The patella in the right knee had, without known cause, slipped out ten years before, and three times since the slipping had been repeated.

Simple conservative measures were advised, and the patient lost sight of until a few months ago, when she reported in response to a note. In the interval the weakness of the knee with slipping had become more frequent and the left knee had also given out. In both the capsule is much relaxed, and the displacement of the patella is so easily produced that there was much apprehension on the part of the patient during the examination lest this should happen. The angle in the line of muscular pull was quite noticeable.

For further treatment an operation was advised in both knees, but as yet it has not been performed.

Case X. Mrs. W. R. F., twenty-seven years of age, was seen first in May of 1902. The patella of the right knee had dislocated when she was eleven years old, and this had been repeated about once a year for five years. After this there had been no actual slipping until one week before the first visit. In the interval of eleven years the patient had always been careful of the knee and most of the time had worn an elastic knee cap.

The examination showed an otherwise healthy person with the capsule of the right knee joint considerably relaxed. The lateral movement of the patella was abnormally free and the displacement to the outside during the contraction of the quadriceps extensor muscle was more than normal. There was no knock knee but well marked flat foot.

For immediate treatment the knee was strapped with adhesive plaster, the flat foot corrected and an operation advised to permanently correct the trouble. As yet this has not been performed.

Case XI. F. M., a young and rapidly growing girl of seventeen years of age, was seen in September, 1900,

because of the slipping of the patella in one knee, which had but just developed.

The girl was growing rapidly and all of the structures lacked tone. The knees were relaxed and the feet also, so that there was marked pronation. This feature was corrected, the knee bandaged and a course of general tonic treatment with exercise advised.

For a time there was marked improvement following the treatment, but of late the slipping has recurred frequently, so that the patient has asked to have the operation performed and is simply awaiting a suitable time.

In considering such a series of cases it is at once obvious that the number is too small from which any positive conclusions can be drawn. At the same time there are certain features which are suggestive for application in the treatment of other cases. In the first place the lesion seems peculiar to girls or young women. It develops at the period of rapid growth, from twelve to sixteen years of age. It may develop either with or without violence. It is usually associated with flat foot, which is probably a factor in the development of the weakness of the knees. True knock knee is sometimes present. In all of the cases the tubercle of the tibia was displaced farther to the outside than normal, so that the line of pull of the quadriceps muscle contained a distinct angle. In the extreme cases without treatment the dislocation may become permanent, as in Case I.

It seems probable that if the condition is seen in the beginning, and the flat foot corrected, together with such treatment as would tend to improve the general tone, that the trouble can be corrected without operation. This has not been possible in any of the cases seen by me, but on general reasoning it seems probable.

If, on the other hand, the dislocation has recurred several times, and the period of osseous growth has passed, the weakness will probably increase unless the faulty mechanical features are corrected by operation.

If an operation is to be considered, the chief point to be borne in mind is the straightening of the line of the pull of the anterior thigh muscles. This is best accomplished by transplanting the outer half of the patella tendon so that it is attached well to the inside of the tubercle of the tibia. If the tendon be too long it can be shortened at the same time the attachment is made. The relaxed capsule is undoubtedly a result of the mechanical pull and can be entirely ignored, the relaxation disappearing as the strain is removed. Of the cases treated, seven were operated upon, and two of the others are awaiting operation. Of the operated cases, four had the outer half of the patella tendon, and one had the entire tendon, transplanted to the inside, and as three had both knees treated, there were eight operations, with normally strong joints in seven, the ultimate result in the eighth being uncertain, as sufficient time has not elapsed since the operation. Of the three cases in which other operations were performed, in one with both knees the capsule was quilted, in one the patella tendon was shortened, without transplantation as well as quilting the capsule, and in one the inner half of the tendon was transplanted as well as quilting the capsule; all relapsed. In one of these a second operation with the transplantation of the outer half of the tendon was performed with a perfect result. In both of the other cases I am very sure that if another operation could be performed, and the tendon transplanted as has been described, the mechanical feature which makes the dislocation possible would be removed so that the slipping would cease.

SCIENTIFIC ASPECTS OF MODERATE DRINKING.

BY FRANCIS GANO BENEDICT, PH.D., MIDDLETOWN, CONN.,

Associate Professor of Chemistry, Wesleyan University.

THE relation of the drinking of alcoholic beverages to the health and welfare of mankind presents several well-defined problems, the study of which has occupied the minds of many scientific investigators in the fields of pathology, psychology and sociology.

The evil results of the use of excessive quantities of alcohol are so obvious and are so noticeably exhibited in all grades of social organization that it is a cause for wonder that in considering the alcohol question so much stress is laid upon the evil effects of excessive use and so comparatively little time devoted to the study of the effects of smaller or the so-called "moderate" amounts of alcohol. To be sure, the fundamental argument that whatever conditions alcohol induces when used in large amounts it must induce in lesser degree when used moderately has been emphasized, but it nevertheless remains a fact that a very large number of individuals use alcohol in moderate amount with no visible signs of deterioration or other untoward effect. Such individuals have long been considered as representing the value of the use, as distinguished from the misuse or abuse, of alcohol; for the enjoyment of the social glass, it has been said, cannot reasonably be considered as injurious to such users of alcohol, and is but a legitimate pleasure that should not be denied a large class of individuals for the sole reason that a certain class, larger to be sure, misuses alcohol.

We speak of moderate drinkers and those that use alcohol to excess; we speak of the use and misuse of alcohol, but is the line between these two degrees, moderation and excess, sharply defined in our minds? In the popular mind at least, a man is not said to drink to excess until he gives some signs of incipient intoxication; until the quantities consumed are sufficiently large to affect the speech or power of locomotion. The use of the visible signs of intoxication as an index of moderate or immoderate use is, however, fundamentally wrong. It is well known that healthy individuals vary widely in their tolerance to alcohol. While the old tippler can drink several ounces of raw whiskey and exhibit

no noticeable effects, the young man unaccustomed to its use may experience headache and dizziness with a single glass of wine.

We may say, in general, that long before intoxication is apparent the user has in nearly every case consumed more than is recognized by all authorities as the limit that is physiologically permissible.

As early as 1864 an English physician, Dr. Anstie, considered that one and one-half ounces of alcohol was the amount that could be taken per twenty-four hours without ill effect. Dr. Anstie's limit is to-day used as the dividing line between moderation and excess by many of the largest life insurance companies in the United States. We find such statements as these in the instructions to medical examiners:

"The daily use of any alcoholic beverage in excess of an amount representing one and one-half ounces of absolute alcohol (Anstie's limit) is not lightly regarded by the home office."

Another paragraph, copied from the medical examination blank of a large life insurance company, is especially interesting, as it endeavors to translate the term 'one and one-half ounces of absolute alcohol" into the equivalent quantities of the various common liquors:

"In reporting 'over-indulgence' in drink, draw the line — since there must be some fixed standard — at Anstie's limit of a daily allowance equivalent to one and one-half ounces of absolute alcohol. Such allowance will be represented, in the case of ardent spirits, by three ounces; of sherry or other strong wine by two wineglassfuls; of claret or champagne or other light wines by one 'pint' bottle; of strong ale or porter by three tumblerfuls; and of light ale or beer by four or five tumberfuls."

Recently we have another standard established by Prof. J. J. Abel of the Johns Hopkins University.

"That there is a 'moderate' or average permissible quantity of alcohol I conclude from the experiments already cited; from the opinions of medical authorities in many fields; from the writings of economists, explorers and military authorities; and, lastly, from my own observations during a long residence in European countries; and this 'moderate' quantity I believe to be represented by one, or at most two, glasses of wine (10% alcohol) or one pint of beer, or their equivalents in terms of alcohol, in the twenty-four hours."

Abel's limit is, it is seen, about one-half that of Anstie.

Even the layman can see that these quantities are very much smaller than those ordinarily required to induce distinct intoxication. Furthermore with those accustomed to the use of alcohol the amount that can be ingested with no visible signs of intoxication is enormous. The following case is not believed to be uncommonly rare, remarkable as it may seem. I give the description as furnished me, prefacing with the statement that I have every reason to believe it correct, for subsequent correspondence has verified every detail.

"I have another acquaintance who is a real first-class 'lusher' and his 'case' I can report on with authority. About three years ago this latter case was boarding in the same house with me and nearly every night he and I played cards together, and it was his invariable habit to 'get outside' of an imperial quart of juice (whiskey) inside of three hours, from 9 P.M. to midnight, and oftentimes another pint on top of that. He never showed any signs of intoxication and was apparently perfectly O. K. in the morning, except his hand was of the 'early morning' variety. Through the day he also took numerous and sundry drinks of more than one variety of cocktails, etc., just how many I cannot say, as I was not with him. His daily quart he kept up from early June till into September, and later in the fall I saw him for several days, when he consumed the same amount. He was about thirty years of age, in apparent excellent health, never drunk to my knowledge, kept up his usual amount with great regularity; his drinking seemed to affect him not at all except shakiness in the morning. I have good reasons for believing he had been keeping this pace up for several years when I made his acquaintance and, so far as I know, still continues. He has, however, grown very stout and not disposed to take any exercise or make any exertion to get about."

Astonishing as these statements seem, it is nevertheless a fact that the large cities supply many such cases, and the use of intoxication, incipient or well-marked, as a measure of moderation or excess appears in the light of such a case distinctly absurd.

The tolerance of persons accustomed to the use of alcohol is no more remarkable than that exhibited by many persons in disease.

It is evident, therefore, that individuality and physical condition play a very important *rôle* in determining what is commonly meant by excess, and in a similar way it can be said that what applies to the state of intoxication likewise applies to the border line between moderation and excess. Moderation for one man may be decided excess for another. In taking into consideration either of the limits set by Anstie or Abel, therefore, we must remember that no general rule will apply in all cases, and one should hesitate very considerably before stating positively that either of the quantities designated by these authorities as "physiologically permissible" could be taken with impunity by all persons.

The first question that naturally arises in considering the effects of moderate drinking is "How does it affect the general health?" Obviously this question needs very careful study. One would naturally suppose that nothing would be easier than to determine this point by asking a large number of moderate drinkers if they noticed any special effect, beneficial or injurious, that they could reasonably attribute to their use of alcohol. A physician would place practically no value on such an investigation, for it is almost universally true that if a man likes alcohol he is

practically sure that, in small quantities at least it does him good.

Where, then, can we turn for impartial information on this most important point? A statistical study of the death-rate in large communities offers an excellent, though recognizably limited, field for study of this question. In hospitals, asylums and public institutions the opportunity is frequently had to secure data regarding the past and present habits of the individual with respect to the use of alcohol, and consequently furnishes the data for determining whether the death-rate is greater among total abstainers or drinkers. It is generally impossible to subdivide this latter class into moderate or immoderate drinkers, and the statistical evidence almost invariably found, *i. e.*, that the death-rate is noticeably lower among total abstainers, does not in reality prove anything except that those who drink to excess raised the death-rate of the class using alcohol.

Perhaps the most elaborate and careful study of the effect of the use of different amounts of alcohol on disease and the death-rate is that instituted by the Collective Investigation Committee of the British Medical Association and republished by the United States Brewers' Association in 1888. The method of investigation was, in brief, as follows:

As a result of a schedule sent to every member of the British Medical Association, 178 replies were received, reporting in all 4,234 deaths. These physicians were asked to copy from their death certificate book data regarding the patients, — occupation, social position, age at death and cause of death, and to indicate to which one of five classes the patient belonged. These classes were: (1) Total abstainers. (2) The habitually temperate, that is, men who drink small amounts and only with meals and rarely take spirits except for medicinal purposes. (3) The careless drinkers — men who without being intemperate or free-drinkers, yet do not confine themselves within a rigid rule; who do not demur to drinking spirits occasionally as a beverage; who may at times drink between meals or even to the extent of intoxication occasionally, but who do not make these practices a habit and, on the average, do not materially exceed what has been termed the "physiological amount" of one and one-half ounces of pure alcohol daily. (4) The free-drinkers — men who drink a fair amount or "take their wine freely," habitually exceeding the physiological amount to a material extent, but yet who cannot be called "drunkards" or considered to have forfeited a character for sobriety. (5) The decidedly intemperate, drinking men, hard drinkers and drunkards.

Though we may not agree with the nomenclature of these different classes, it is certainly obvious that considerable care was taken to segregate the users into fairly well-defined classes. It is very much to be regretted that the data regarding the first class are practically valueless, as it comprised less than 3% of the total number of cases. The conclusions that have to do with the general question we are considering are:

"That habitual indulgence in alcoholic liquors beyond the most moderate amounts has a distinct tendency to shorten life, the average shortening being roughly proportional to the degree of indulgence.

"That total abstinence and habitual temperance augment considerably the chance of a death from old age or natural decay without special pathological lesion."

It is a digression that is, perhaps, warranted if reference is made to the present status of alcohol in medicine. In March, 1902, a meeting of the Suffolk District Medical Society was held in Boston, and a number of papers were read on the use of alcohol in therapeutics. In June, 1902, the annual meeting of the Massachusetts Medical Society was devoted to alcohol in therapeutics. The November (1902) number of the *Practitioner*, an English medical journal of high repute, is devoted to this question, and while there are arguments on both sides, the overwhelming opinion is that alcohol has been accorded a false position in therapeutics.

Alcohol is not going to be entirely discarded. It never will or never should go, as it is a therapeutic agent of great value in certain cases, but its rational use is to be very much more circumscribed than ever before. One very typical example of the change in opinion and custom is furnished by the records in the Massachusetts General Hospital in Boston, which used, in 1884, alcoholic beverages per patient per year to the amount of $1.84, while in 1900 this amount had fallen to 29 cents per person per year.

The therapeutic action of alcohol is not primarily connected with the question we are discussing, — the moderate use of alcohol as a beverage, — but as many use alcohol on the pseudo-basis that it is "good for the health," it ought to be clearly stated that the most progressive medical men are changing their views radically regarding the use of alcohol as a tonic, aid to digestion, heart stimulant, etc. It has been a source of wonder to physicians that so few cases of alcoholic excess are attributable to the initial use of alcohol medicinally. This is undeniably true, but we Americans are notorious self-dosers, and it is certainly true that a large amount of alcohol has been taken, in a sense as a medicine, as an aid to digestion or as an appetizer. It is to be feared that the small percentage of alcoholics arising from alcohol prescribed by physicians would be many times multiplied from alcohol self-prescribed. Alcohol from the therapeutic standpoint of the best medical authorities is primarily a narcotic, and self-dosing with it cannot be countenanced by the medical profession.

We have seen the difficulties in ascertaining the effects of moderate drinking by the direct questioning of individuals, and we have seen that vital statistics in general are capable of a wide degree of interpretation, the chief element of error being the inability to distinguish satis-

factorily between the moderate and excessive users. If, however, instead of taking the vital statistics of a whole community, we take a class of selected lives in which, so far as possible, the excessive drinkers are eliminated and if, furthermore, we have means for distinguishing between the total abstainers and the moderate drinkers, data of much greater value for the question we are discussing may be accumulated. Almost ideal conditions for this differentiation obtain in the statistics of the great life insurance companies, for, as a recent writer in a medical journal strongly phrases it:

"Whatever difference of opinion there may be between the temperance fanatic and the tippler, the W. C. T. U. and Lincoln, as regards General Grant's special brand of fighting whiskey; the army canteen; drinking toasts in the White House; the traditional centenarian, whose chief diet is whiskey and tobacco; or the theory of alcohol as a food—I repeat, whatever opinions may exist on these and kindred topics, one thing is certain, — the financiers all over the world who have their money invested in life insurance companies all agree that drinkers belong in the class of hazardous risks."

In life insurance statistics we have the best separation of heavy drinkers from moderate drinkers that it is possible to make, as is shown by an examination of the conditions under which men are accepted as risks by life insurance companies. It has been said by medical men that a few companies will insure anything this side of the grave, but it is nevertheless a fact that the large number of the old line companies exercise every precaution to examine an applicant thoroughly and eliminate the hard drinkers.

The following questions are taken directly from the printed form of application for a policy in a large life insurance company, and are practically a copy of those used by all the large companies:

"Do you ever use or have you ever used wine, malt liquors or any alcoholic stimulant? If so, which, when and in what daily quantity? Have you ever used any of them to excess? Describe particularly your past habits in all these respects. Have you been or do you intend to be engaged in, or connected with, the manufacture or sale of intoxicating drinks or liquors? Have you been treated for alcohol or narcotic habit?"

The examining physician is also called upon to answer:

"Does applicant use beer, wine or other alcoholic stimulants daily and habitually? If not daily, how often? What is used and how much? What have the past habits been in this respect? Have any of them ever been used to excess? Are there evidences of impaired health or constitution from use of stimulants or narcotics? Has applicant taken treatment for alcohol or narcotic habit?"

In a special statement to medical examiners printed on the reverse of the policy we read: "The applicant's habits regarding the use of alcoholic stimulants . . . should be definitely ascertained, and in stating them in your report avoid the use of such words as 'moderate,' 'occasional' and 'temperate.' Where their daily or frequent use is suspected, assure yourself that the stomach, liver, kidneys and nervous system are free from any evidence of injury."

If the number of questions is a fair index, much more importance is now laid on the applicant's relation to the use of alcoholic liquors than twenty years ago.

In spite of every precaution, a number of heavy drinkers are able to get insurance, and a large number of the lawsuits over insurance matters are on the ground of the excessive use of liquors and therefore a violation of the part of the contract covering the applicant's answers, for those answers are now made a definite part of the insurance contract, and hence greater care must be exercised on the part of the applicant to avoid any chance for suspected fraud.

It is the custom of many of the large life insurance companies to keep an eye on the physical condition of their risks. This shows that there is at least an effort made to keep out the hazardous lives, for in such cases the companies lose no opportunity to drop the risk and refuse to reinstate him after an overdue premium.

Consequently it seems a fair statement that those carrying life insurance are selected lives; the proportion of heavy drinkers is kept at a minimum; and that no statistics as yet available separate in any better way the moderate from excessive drinkers in a community.

The further segregation of risks into the two classes, abstainers and non-abstainers, has not been common, at least in this country, though there are several societies in England that have done this for a number of years. Obviously, a study of the death-rate of total abstainers and the moderate drinkers would give the best comparisons of the effect of the moderate drinking of alcohol upon health.

The office having the largest experience in abstainers' lives is the United Kingdom Temperance and General Provident Institution, which was established mainly by Friends in 1840, and has accumulated funds amounting to about $30,000,000. It is one of the largest English mutual companies. For a number of years after its establishment, only abstainers were admitted. Later on the lives of carefully selected moderate drinkers were accepted, but the two classes were kept separate and distinct, and the bonus or profits awarded each five years to the members of the two classes. During the past thirty-five years (1866–1901), the general average ratio of actual to expected deaths in the total abstinence section has been 24.7% less than that in the general section. The bonus was correspondingly greater in the temperance section. Similar results are reported from all the other companies making this distinction between total abstainers and moderate drinkers.

In the American companies very little data are at hand. The most elaborate investigation was carried out under the direction of Dr. Emory McClintock, actuary of the Mutual Life Insur-

ance Company of New York in 1895. In his report on the results of his investigation, Dr. McClintock says: "The abstainers show, therefore, a death loss of 78% of the maximum and the non-abstainers 96%." This difference in favor of the abstainer is slightly lower than that of the English companies. While undoubtedly there may be a valid question raised as to what proportion of this favorable death-rate is due to general good habits irrespective of the use of alcohol, the difference of nearly 25% in the English companies and of 18% in the investigation of Dr. McClintock is obviously altogether too large to attribute wholly to habits other than that relating to the use of alcohol.

Just what is scientific and what is not is sometimes difficult to state, and although personal opinions founded on impressions can hardly be considered as scientific, in accumulating the material for this paper I have had considerable correspondence with a number of insurance authorities, all high officials in the large old line companies, whose opinions surely are worthy of consideration.

A physician, president of the medical board, writes: 'We have on several occasions endeavored to utilize the statistics in our possession, but have found it difficult to arrive at any satisfactory conclusion, save the general one that anything but the very moderate and occasional use of liquors is prejudicial." (Oct. 28, 1902.)

The president of another writes: "As between the two classes (total abstainers and non-abstainers) we know there is no question that the total abstainers are the better risks." (Jan. 26, 1903.)

From the actuary of another we have much the same: "Personally I am convinced that the mortality among total abstainers always has been and always will be less than among moderate drinkers of alcoholic beverages." (Oct. 15, 1902.)

A recent writer in the *Spectator* the recognized organ of the life insurance business says: "It is now becoming generally recognized that the alcohol habit is one of the main factors in determining the length of life. No life office will knowingly accept the proposal of any one known as a hard drinker. Evidence of a very striking kind is rapidly accumulating which shows that even the moderate use of alcohol is prejudicial to health and longevity. In England about a dozen life offices recognize this fact in one of two ways: (1) By giving a reduction of premium to abstainers, or (2) awarding them a larger share in the profits. Last year the Sun, one of the oldest life offices, established in 1810, opened a special section for abstainers, giving them a reduction of 5% in their premiums. When the Sun life office announced a reduction in premiums for abstainers, *The Financial Times*, commenting on the fact, said: 'A battle has long ranged round the figures of those offices which keep their men in separate sections and always show a higher bonus to the longer-lived abstinent. Strenuous efforts have been made to minimize these important statistics, and it is quite likely that they do not mean all that has been claimed for them, but when we see a first-rate company like the Sun offering a direct and immediate cash bonus to abstainers, it looks very much as if the case had been proved.'" (Aug. 22, 1901.)

Among the multitudinous effects of alcohol on the human organism, none is so characteristic and invariable as that upon the higher senses. Professor Abel says:

"The best bred man indulging in wine with permissible moderation no more escapes the minor psychical changes induced by it than does its meaner slave fail of its sense-destroying power when he drinks 'till he remembers his misery no more.' In the case of the former the mental changes induced will never attain the degree when self-respect and social conduct are outraged and they will pass unnoticed by all except those who are keen observers of their own mental states."

The effects of the smaller or moderate doses on mental activity are generally no more apparent to the ordinary observer than are the effects of similar quantities on health or length of life. To the trained observer in the psychological laboratory, however, small quantities of alcohol produce certain well-marked and characteristic phenomena in the brain action that should be very carefully and clearly stated to the general public, for they play a very important *rôle* in determining a man's efficiency in the struggle for existence. The lesser psychical effects of alcohol were not clearly defined until the experimental psychologist elaborated his methods for studying the mental state of man. By means of certain forms of apparatus and tests to be found in every psychological laboratory, it is not difficult to determine with reasonable accuracy the mental activity of an individual. Any variation from the normal is easily detected, and consequently the work of experimental psychologists, especially Kraepelin and his school, furnishes reliable data for a consideration of the effect of alcohol on these higher mental processes. The initial apparent mental stimulation immediately following the ingestion of small quantities of alcohol observed in some of the simpler tests was generally followed by a retardation period which resulted in a sum total of depression, and with the types of mental activity involving constructive operations, the time required for the completion of the mental process was lengthened from the first.

These results on small quantities of alcohol taken in a single dose are, however, not of as much importance or have not the significance of those experiments in which the alcohol was administered in small quantities for a considerable period of time. In the experiments of August Smith, the amount of alcohol used was about two and one-half ounces per twenty-four hours, and his data admit of no other possible deduction than a noticeably inferior mental activity, which, indeed, was apparent after eight days of abstinence.

In general, we may say that alcohol diminishes

all forms of mental activity. The different phases of this process are very complex, but the accepted explanation of to-day is that alcohol paralyzes the inhibitory functions, and the reserve naturally acquired with age is cast off; a spirit of recklessness and of disregard of consequences is developed. If larger amounts of alcohol are taken, the speech becomes freer, a feeling of egotism is paramount and doubtless more than one brilliant speech has been *delivered* under this apparent stimulus, though in its *preparation* the effect of alcohol could have been but deleterious. As the quantity of alcohol ingested becomes larger, the subject becomes loquacious, boisterous, careless of speech, a coarseness and vulgarity enters into his remarks and finally the speech becomes thick and unintelligible, locomotion becomes impossible and a deep coma is induced. The last acquisitions of mature man are the first to be affected, the first movements of the child the last to give way to the action of alcohol. All these effects, from the retardation of mental processes by small quantities to complete intoxication by larger amounts, form a perfectly connected series of phenomena of alcoholic narcotization.

The consideration of the paralyzing action of alcohol on mental processes brings us face to face with one of the most important phases of the struggle for human existence. By just so much as alcohol in large or small quantities diminishes mental activity, by just so much does it handicap the man whose keenness of perception and manipulative skill are absolutely essential to him in this day of the sharpest competition known in the history of the world. The brain incipiently narcotized is not a normal organ; a man is not that complete master of himself that he must be to succeed, with that most intricate organism, the brain, imperfectly functionating. Smith tells us that quantities of alcohol of about two and one-half ounces retarded brain action even after a week of abstinence. Other observers have noticed this lasting effect, and Professor Cushny points out that if this is true many habitual drinkers, even if using moderate amounts, are persistently narcotized and never their real selves.

One of Kraepelin's pupils, Aschaffenburg, contributed greatly to our knowledge of the influence of alcohol on practical work involving mental processes by his experiment on the effect of one and one-quarter ounces of alcohol on four typesetters. This form of work is peculiarly adapted to the study of questions of this nature. The subjects were all accustomed to the use of beer, but abstained for the experimental period. Every detail was so perfected that the test was scientifically accurate and simultaneously adapted to the practical every-day life of the men, with the single exception of enforced abstinence. On the second and fourth days, each man was given one and one-quarter ounces of alcohol in the form of a Greek wine fifteen minutes before the regular working test began. Although there were no more errors than usual, the amount of work done with alcohol was 15% less than that done without it. Here we have a complete scientific demonstration of the effect of a so-called moderate amount of alcohol (Anstie's limit) on the efficiency of labor.

This brings us to the very important question of the relation of the efficiency of labor to the success of employer and employee alike. America, by reason of her progressiveness and ingenuity, occupies a prominent position in the manufacturing industry of the world and consequently the deleterious action of even small amounts of alcohol on mental activity and efficiency must be carefully guarded against in order to avoid the handicap the English workman has by reason of his custom of drinking alcoholic liquors during working hours. We are told that the recently returned Mosely commission has emphasized this point in comparing American and English workmen. That our manufacturers have been alive to this question is evident from the report of Commissioner of Labor Carroll D. Wright on "Economic Aspects of the Liquor Problem." Of the 7,000 establishments examined, over 75% in employing new men were accustomed to give consideration to the habits as to the use of intoxicating liquors, and more than half made some requirement that all employees or employees in certain occupations shall not use intoxicating liquors.

In response to a letter asking for the rules of the New York, New Haven & Hartford Railroad regarding the use of alcoholic liquors by employees, the following was received from the office of the first vice-president:

"In our book of rules for the government of the operating department we have a rule reading as follows: 'The use of intoxicants by employees while on duty is prohibited. Their habitual use or the frequenting of places where they are sold is sufficient cause for dismissal.'" The writer adds: "This, I believe, is the almost universal practice on railroads in the United States." (Dec. 24, 1902.)

Applicants for employment on the Boston Elevated Road are required to take oath that they do not use intoxicating liquors, if such is the case. Those not taking this oath are not considered. The rules of the company concerning the use of liquor are as follows: "If a car service man is known to enter a saloon in uniform, he is suspended from work for seven days. If he enters a saloon in uniform a second time he is discharged. If he is known to be intoxicated, whether on duty or not, he is discharged."

It is clear that at least in certain employments strict measures are adopted to insure the highest efficiency by practically prohibiting the use of alcohol, for that is what it really amounts to in a large number of cases. A man cannot use alcohol and retain his position. I believe that this action on the part of employers of labor will become more and more universal, for a problem involving so great social and economic interests as the effect of the moderate use of alcohol on the efficiency of labor is sure to attract increas-

ing attention. All employers cannot do as Mr. Carnegie is reported as doing, that is, give each employee a check amounting to 10% of his yearly wages if he can truthfully say that he did not touch intoxicating liquors during the past year, but certainly the increased efficiency and the reliability that is exhibited in a marked degree by the abstainer is sure to tell in the amount, if not the quality, of his production, and ultimately this fact will have to be recognized by all the employers.

Two years ago I heard a young clerk remark that in Boston it was considered decidedly unwise for a bank clerk to use beer or wine at his noon lunch. The following letter from one of the best-known banking men in Boston is self-explanatory: "I know one bank teller who lost his place because the directors knew that he frequented an ale and beer counter for his lunch and took those drinks with the food.

"I know a bank bookkeeper who had been marked for the cashiership of another bank, but the president of the latter, going to New York on the same boat, saw him using similar drinks and concluded that he would better not take the risk. The president afterwards stated this in my hearing. Of course individual opinions differ in that matter as in all others, but the practice is not looked upon with favor by bank managers, at least in Boston." (Oct. 29, 1902.)

A personal letter from a railroad president, probably one of the finest examples of a man living the strenuous life, throws an interesting light on the moderate use of alcohol and the relation between employer and employee:

"I more and more hear it said by business men that the business man of the future must be a total abstainer. It is very generally the practice now, I think, for men who take wine at dinner not to take anything at luncheon or during business hours. This would seem to indicate that the use of alcoholic liquors is considered on the whole injurious. It is well known, also, that so far as employees are concerned, all large employers establish rules which make it practically impossible for an employee who uses liquor to remain in the service." (Dec. 30, 1902.)

The president of a large life insurance company writes in a personal letter, the phraseology of which is so telling that I give it in detail: "More and more does the man who works with either his head or his hands need for the efficiency which is absolutely demanded of him that clearness and steadiness which is possible only to a high degree of temperance; and the man who impairs his efficiency and loses time through indulgence is walking toward the door that will shut him out from promotion and even employment. Men, whatever their position or range of their capacity, cannot in these days afford to be at less than their best." (Jan. 26, 1903.) Such statements as these have a force and significance that must demand attention. The experience of the large employer of labor verifies in the smallest detail the deductions of the psychological laboratory — that the moderate use of alcohol diminishes a man's efficiency.

The fact that a large number of individuals become so addicted to the use of alcohol that it requires all the skill of the medical profession, accompanied by every known psychological aid, to combat the self-destroying appetite, demands a careful consideration of the danger of acquiring the alcohol habit as a result of its "moderate" use. Just what the alcohol appetite is has been the subject of much discussion in medical, sociological and psychological journals. That it is hereditary is in opposition to Weissman's theory, and probably we must admit that a craving for alcoholic liquors is not directly transmitted from parent to child. That the resistance of the individual to the narcotic effects of alcohol is lowered by the alcoholic progenitors seems to be much more likely to be the case. The idea that a craving is transmitted has, as Partridge points out, unquestionably done an incalculable amount of harm by relieving the individual of a sense of moral responsibility. "The belief that a habit is incurable does more than anything else to compel its continuance." The theory that the moderate use of alcohol can transmit a craving for alcohol would hardly seem plausible; but that the resistance to the strong impulse to use alcohol after acquaintance with it may be weaker in the progeny of moderate drinkers is in no sense an unreasonable assumption, though lacking in absolute proof.

That the use of moderate quantities of alcohol has a strong tendency to lead to its excessive use is a matter of common observation. To what extent this acquisition of the alcohol appetite prevails is very difficult to estimate, for unless a man drinks to intoxication we have no means of knowing the quantity used. The only statistical data at hand are those by Neison, quoted in Sieveking's "Medical Adviser in Life Assurance." There it is estimated that there is one drunkard for every 74 of the male population, and a footnote by Sieveking adds, "We fear that more recent investigations show even a larger proportion." In the investigation of the British Medical Association previously referred to, we have, of the 4,234 cases, all over the age of twenty-five years, 30% decidedly intemperate and 15%, or one in six, very hard drinkers.

If these proportions are generally true, the danger of the habit-forming tendency of alcohol is indeed a real one. Furthermore, as we have seen, long before the drunkard stage has been reached, the individual has passed the most liberal estimate as to what is moderation, and is drinking to excess. Consequently we may *very conservatively* estimate that one in 50 of our male population uses liquor to excess and has a well-defined, though not necessarily absolutely, uncontrollable appetite for alcohol. A physician with a large practice, an instructor of twenty-five years' standing in one of our largest medical schools, in answer to a request for his opinion on the habit-forming tendency of alcohol says: "In my experience the habit-forming tendency

has been so apparent in every single individual that I do not think it can be for an instant questioned. I have seen so many times the teaspoonful of whiskey or the half glass of beer or the little glass of wine taken at a regular time so looked forward to and so many times gradually increased, and I have had to interdict the use of it, that I cannot feel this is a thing which can be questioned for a moment, that any amount of drinking, no matter how small, invariably tends to form a habit which inevitably tends to increase." (Oct. 22, 1902.)

The medical director of a large life insurance company writes: "The great trouble (with occasional drinking) is that a young man may get into the habit of taking some form of alcohol every day, and in this I include beer and ale, and as he grows older he may feel the necessity for a larger amount, and before he realizes it he has become an habitual drinker." (Oct. 20, 1902.)

Certainly it is not unreasonable to conclude from this evidence that there is a real danger from the habit-forming tendency of alcohol — a danger that we should not overlook in any consideration of the use of alcohol.

We can now more intelligently consider the conditions existing in actual life and determine in how far the moderate use of alcohol is compatible with scientific deductions. Obviously, we must very decidedly alter our views regarding what is moderation and what is excess. Certainly Abel's limit of one pint of beer per day is not too conservative. Indeed, the facts here collated would lead to the emphatic discountenancing of the *habitual* use of alcohol in any amounts. We may say with entire reason that many of our best citizens, men the products of whose brains have furthered our commerce and industries, literature, science and religion, have used liquors in moderation and perhaps habitually all their lives and yet are apparently not injured by them. But such men are, in fact, but a very small proportion of our male population, and we must consider the effect of moderate drinking not only on a select class of men, whose very success in life has shown their superior ability to exercise judgment and restrain upon their impulses and practices, but we have to consider its effects on the average man.

Dr. J. S. Billings has, at the instance of the Committee of Fifty, prepared a statement of the result of a series of questions submitted to 900 men of the type designated above as "selected." They were the typical brain workers of the United States. Accompanying the schedule returned with the answers, a number of individuals added paragraphs expressing their personal opinion. The same differences of opinion invariably found in an investigation of this nature are here present, though the general opinion is to the effect that the use of alcoholic drinks as a stimulus to mental effort gives bad results, although they may be agreeable as restoratives in fatigue.

Thus these data indicate that even to the select class of men the moderate use of alcohol is, on the average, of doubtful benefit, and we see here nothing to alter our view that the *habitual* use of small amounts of alcohol cannot be considered innocuous even to the select class of men. As regards the *occasional* use we may say that those men over forty, whose self-restraint is such as to insure that "self-respect and social conduct" are never outraged, who use *occasionally* the glass of wine with the last meal of the day and after the important work of the day has been done, are the individuals whose use of alcohol is least incompatible with the teachings of science.

With the average man, and especially with the young man, the case is very different. The average man, with perhaps a family or relatives dependent on him, should not jeopardize his chances for success by the use of alcohol. The diminution in mental and muscular power invariably accompanying the use of even small amounts of alcohol is a potent factor in determining his efficiency, chance for promotion and appreciation by his employers. Clearness of thought, quickness of perception, keenness of sight, deftness of touch, skill and accuracy in manipulation are valuable assets of the successful man, and each and all of these factors are so immediately affected by the use of alcohol as to practically interdict its use with men whose ambition leads them to hope for and strive for the best in life.

Statistics show that the drink habit is formed most frequently between the ages of fifteen and twenty-five, and it is with the young man that special pains should be taken to show clearly that any use of alcohol, even though it be occasional, must be regarded as contrary to scientific teachings. While alcohol in small amounts does not produce any demonstrable changes in the tissues, it certainly does retard the physical and mental growth of youth, for the growing organism is especially susceptible to the injurious effects of alcohol. The habit-forming tendency of alcohol is, as has been stated before, a factor in the moderate use of alcohol that it is absolutely necessary to take into consideration. No man need fear an inherited craving until he first tastes alcohol. As Partridge says, it is inconceivable that a person can crave a thing that is outside of his experience. Because the father was a heavy drinker it is, however, absolutely necessary for the son to abstain wholly would he avoid the great danger of forming a habit.

In general, while the impulses are uncontrolled by that reserve acquired with age, the danger of forming the habit must always be recognized, and by acquiring the alcohol habit I do not necessarily mean to the degree that the user becomes a miserable sot, but the feeling of the need of any amount of alcohol regularly — a feeling that can be considered in no other way than an injurious habit, sure to be followed by a train of physical and mental misfortunes that distinctly incapacitates the sufferer for the normal life of man.

THE USE OF OBSTETRIC FORCEPS.

BY WARREN R. GILMAN, M.D., WORCESTER, MASS.

AT first thought it may seem a waste of time to ask attention to remarks on the use of obstetric forceps, for almost all men in active practice use the forceps freely and without hesitation, and there are few, I fancy, who seriously question their own skill in the use of the instrument. The frequency with which we use the forceps gives confidence, and in many cases causes a certain amount of carelessness. There is danger that we may ignore the fact that serious harm may be done both the mother and the child.

In my own work I am obliged to criticise my skill not infrequently, and I feel sure, from my observation of the work of others, that due care is not always used and that the principles of the mechanism of labor are not always given proper consideration. There is the danger that we may come to look upon the forceps as a simple and harmless instrument of traction; to think that it is only necessary to grasp the head — no matter in what way — and then pull until delivery is effected. At times it seems as if some men look upon the head as a round, inanimate body which is to be pulled through a perfectly straight, cylindrical tube. If five pounds of traction is not effective, ten pounds is applied; and so on, the only limit being the strength of the man who holds the forceps. I believe, however, that the men who rely upon strength alone and use little or no skill and care are the exceptions. Most men have it in mind that an undue amount of force may do harm, and try to apply and direct the force used according to what they believe to be the proper method. When moderate traction fails to deliver the head, there is a tendency to ignore the art of forceps delivery and fall back upon brute strength. Instead of stopping, examining the situation carefully and perhaps reapplying the forceps, many men become unnecessarily worried, and decide that the child must be delivered at once. Delivery is usually effected, but the operator often has little reason to congratulate himself upon a skilful operation. No one denies that serious harm is sometimes done by the ignorant and careless use of forceps. There is no doubt, also, that the man who uses the instrument carefully and skilfully sometimes inflicts injuries upon the mother or the child.

Forceps extraction is a serious operation in certain cases, and the results are not always satisfactory. Skill in the use of forceps can be acquired only by practice, and it goes without saying that a young practitioner should begin his training with the low forceps operation. When any marked delay occurs in the labor of a multiparous woman after the head has reached the perineum, there is opportunity offered for the use of forceps. In such cases there is usually a well-dilated and relaxed outlet, and there is hardly a possibility of doing any harm. Here one can gain familiarity with the instrument and learn the " feel " of the forceps blade as it glides into proper position upon the side of the head. The forceps should be applied with care and precision even in these simplest cases; and traction should be intermittent and under good control.

It is of the greatest importance that the exact position of the head be determined in every case before the forceps is applied. Neglect of this detail is the chief cause of failure in many attempted forceps deliveries. It is not enough to know that the head presents. The exact position of the head in the pelvis should be determined, and the degree of flexion or extension of the head made out. The more of the necessary information which can be obtained by external examination, the better; but it must be obtained, even if the whole hand has to be inserted into the vagina or uterus. When one is ready to apply the first blade of the forceps, he should be able, so to speak, to see the inside of the pelvis and apply the blades exactly in the proper position.

I have seen the forceps applied so many times when the operator did not know whether the occiput was anterior or posterior, and had made no attempt to find out, that I feel it proper to emphasize strongly the importance of the careful preliminary examination. A man who has not at least a fair amount of skill in making out the position of the head has no right to use the forceps.

I do not wish to discuss the indications of forceps at this time. There are certain conditions which demand forceps interference at once; but there is more or less uncertainty in a large number of cases as to the necessity of such interference. The man who is skilful in the use of forceps is warranted in using the instrument earlier and oftener than a less experienced person. His skill often saves his patient an hour or more of suffering. A poor operator should hesitate to interfere except in the simplest cases; for the saving of a few hours of labor pains hardly compensates the woman for serious laceration of the vagina and perineum.

Laceration of the genital canal is to be guarded against in every labor case for reasons too well known to need enumeration. There are emergencies, however, when it is necessary to deliver at once; and at such times one should not be deterred by the prospect of even serious lacerations, if the life of the mother or the child is at stake.

The term " low forceps " is used when the head has descended far enough to rest upon the perineum. If the head has rotated forward, the application of forceps is not difficult as a rule; but in a primipara, with a head crowded down upon the perineum, and a large caput succedaneum presenting, more or less difficulty may be met at times.

The fingers of the right hand guide the left blade into place along the left side of the pelvis and direct it to its proper position over the left ear. The peculiar motion of the forceps blade as it glides over the head is difficult to describe, and has to be learned by practice. The left blade is held in position by an assistant and the

right blade introduced upon the fingers of the left hand, which guide it to place on the opposite side of the head. If this blade does not lock easily, it should be reintroduced and brought to the proper position. The forceps when locked grasp the head in the occipito-mental diameter, and in low forceps one should not be satisfied with any imperfect or oblique grasp of the head.

Traction should be made forward until the occiput clears the symphisis; then the handles are raised and the head extended over the perineum. The perineum should be dilated slowly by intermittent tractions, the head being allowed to recede between them. It is my custom to remove the forceps when the head has thoroughly dilated the perineum. With the patient on her left side, the thumb behind the anus pushes the head forward over the perineum, and delivery of the face is accomplished as in normal labor.

If the head is delivered by the forceps, there is a little more danger of hurrying the passage of the face over the perineum.

When the occiput is posterior at its engagement in the pelvis, it usually rotates to the front. The mechanism of this rotation has been well described in a recent article by Gossett in the *American Journal of Obstetrics*. When the occiput remains posterior, even after reaching the floor of the pelvis, delivery sometimes occurs spontaneously; but very often it is necessary to deliver by forceps. The occiput usually lies at the right of the sacrum, and the blades of the forceps should be applied to the sides of the head; the left blade over the right ear, which is posterior, handle slightly elevated to grasp well back on occiput; the right blade over the opposite side of the head in a position which allows easy locking. Traction should be downward and backward as far as the perineum permits. Rotation of the occiput to the front sometimes takes place even toward the last of the second stage and during extraction with the forceps. Any tendency of the head to rotate must be watched for and favored. If the handles turn more and more toward the left, the rotary motion may be helped slightly. If the occiput rotates until the sagittal suture is directed to the anterior part of the pelvis, the forceps should be removed and reapplied as in ordinary cases of occiput anterior.

If there is no rotation to the front, traction is directed backward until the root of the nose passes the symphisis; then the handles are carried up as the occiput comes out over the perineum. In these cases extraction is more difficult, and there is more likelihood of tearing the perineum than in occiput anterior delivery.

The term " mid forceps " is used when the greatest diameter of the head has passed the superior strait and the lowest part of the head has not reached the floor of the pelvis. When the head is in this part of the canal the sagittal suture lies in an oblique diameter as a rule, but is sometimes transverse.

With the occiput in the left anterior position, the right hand is introduced along the left side of the pelvis and the posterior ear located. The left blade of the forceps is introduced on the hand and applied over the ear. The right blade is slipped into the opposite side of the pelvis on the fingers of the left hand and brought into a position which permits easy locking. If the blades do not lock at once, the right blade must be reapplied. The left blade has been applied by touch in the proper place and the right blade must be adapted to the opposite side of the head; in order to lock with the left blade, the right has to be rotated slightly forward toward the front. No change must be made in the position of the left blade after it has been properly placed.

In occiput right anterior position, the blades are applied in the same way; but the right blade is placed carefully over the posterior ear and the left blade rotated somewhat to the front to lock properly. In all cases care must be taken to keep the guiding fingers inside the cervix, so that the blades are passed between the cervix and the head. Traction is made downward until the occiput clears the symphisis, as in low forceps. The moderate rotation from left or right to the median line is to be favored.

When the head lies in a transverse position the application of the blades to the sides of the head is a very difficult matter and is sometimes impossible. When applied in this way, the posterior blade lies in the hollow of the sacrum and the anterior blade lies in the median line beneath the symphisis. The difficulty of applying the forceps in this manner is so great that many men advise against the attempt and apply it to the sides of the pelvis. When the blades are applied to the sides of the pelvis, they grasp the transverse head in the occipito-frontal diameter and in locking there is a good deal of pressure exerted upon the head. In transverse positions it is my custom to apply the blades to the pelvic curve and then attempt to rotate them into position on the sides of the head. If much difficulty is met, I am satisfied with an oblique grasp of the head: one blade over one temple and the other over the opposite posterior parietal region.

If it is found, after locking the blades, that the handles do not come into complete apposition, undue compression of the head may be avoided by placing a folded napkin between the handles. It is especially important in these cases to use tentative traction at first, to see if a firm grasp has been secured. As the head is brought down toward the perineum, forward rotation is to be expected and favored; when it has taken place, the forceps should be reapplied or slipped into the more desirable position on the sides of the head.

In describing the use of forceps on the head which lies with the occiput to the rear, I will consider the position O. D. P., since that is much more common than O. L. P. The progress of labor in these cases is usually slow and the head somewhat extended. Forceps delivery is indicated more frequently than in anterior positions.

The right hand is introduced into the left side of the pelvis, inside the os, and the fingers locate the posterior ear. When the hand can grasp

the head an attempt should be made to turn the occiput to the front. In a certain number of cases this is successful, and the head is then in a much more favorable position for the application of forceps.

If manual rotation cannot be accomplished, the left blade of the forceps is slipped in upon the fingers of the right hand until it is in the proper position over the posterior ear. On the left hand as a guide, the right blade is passed in on the right side of the pelvis and rotated forward slightly until it locks easily.

Traction is made downward until the head reaches the floor of the pelvis. Rotation of the head to the transverse and then to the anterior position is to be helped. If the blades of the forceps have been properly applied, it is safe to use considerable force in helping rotation, and a good operator can often bring the occiput to the front. When this has been accomplished, the forceps will have been completely inverted and the tips will be found to lock backward into the hollow of the sacrum. The instrument should then be removed and reapplied to the occiput, which lies in the right anterior position. Extraction then proceeds as in an ordinary low forceps case.

When the occiput is posterior and the head extended, the application of the forceps in a reversed position is strongly advocated by many. The blades are applied to the occipital end of the head, with the tips directed to the back of the pelvis. Traction should be gentle and exerted only until flexion of the head is brought about. After the head has been flexed, the grasp of the forceps in the reversed position becomes very insecure and further traction is not to be made. This procedure is directed solely to the securing of flexion, and is not a method of delivery.

In some cases the attempt to rotate the occiput to the front is not successful, and the occiput settles into the hollow of the sacrum after it has reached the floor of the pelvis. Delivery must then be carried out as described in low forceps operation on persistent occiput posterior.

The term "high forceps" is used when the largest diameter of the head has not passed the superior strait. The head may be free above the strait, or just entering the canal. The high forceps operation is very difficult, and, in the hands of any but the most experienced, dangerous for both mother and child. When the head floats, or the largest diameter of the head does not come through the superior strait, I very much prefer version to forceps. With the average practitioner the results of version are much better. In such cases one's attention should be directed to keeping the membranes intact until he has decided upon his course of action. If the membranes are ruptured and the uterus contracts upon the body of the child, version is dangerous, if not impossible.

When the head has engaged, the forceps should be applied as in the mid-forceps operation. The blades are passed in along the sides of the pelvis and then adapted to their proper positions on the sides of the head. It is often impossible to place them in perfect position, and one has to be satisfied with an oblique grasp of the head: one blade over the temple and the other over the posterior parietal bone. As the head descends, they may be changed to a better position on the sides of the head.

When the head floats and refuses to engage in spite of good pains, there is probably some disproportion in the size of the head and the canal; and the head is partly extended. It is evident that the application of the forceps blades to the sides of such a movable head must be extremely difficult. Most men agree that it is not only almost impossible, but is undesirable. The blades should be applied in the oblique diameters of the pelvis, when there is room for them.

When the head lies in a transverse position, as is often the case, forceps blades placed in position on the sides of the head would shorten the conjugate diameter of the pelvis when this very diameter is probably already too short to allow natural engagement. For this reason it has been the custom to grasp such a head obliquely. A writer in the *American Journal of Obstetrics* for January, 1903, takes exception to the universal application of this rule and describes a method of applying the blades to the sides of the head and delivering successfully.

In median and high forceps operations the condition of the os plays an important part. Care must always be taken to apply the forceps within the os. The cervix must be enough dilated to permit the application of the forceps and allow the passage of the head; for extraction through a firm, partly dilated os results in severe lacerations.

When the head is in the upper part of the canal, and more especially when it has not engaged, extraction with ordinary forceps is difficult and a good deal of force is often necessary. Traction from the handles drags the head against the symphisis and much of the force is wasted. There is also the danger of injury of the soft parts of the mother. In order to exert traction downward in the proper direction, the following method is to be employed: With one hand traction is made from the handles, while the other hand presses downward strongly on the forceps at the lock. In this way the lock acts as a fulcrum and the pull is downward instead of forward against the symphisis.

Extraction of a head high in the pelvis is much facilitated by the use of the axis-traction forceps. With this instrument traction is exerted almost in the axis of the superior strait: less power is needed because very little is wasted in friction against the symphisis. A very good substitute for the Tarnier axis-traction forceps is the axis-traction rods, which can be attached to the ordinary forceps.

In high-forceps operations it is especially important to determine the exact position of the head; and in extraction the mechanism of normal labor must be borne in mind. Flexion and

rotation of the head must not only not be hindered, but must be helped.

The forceps should be reapplied as soon as any change in the position of the head offers a chance for a better grasp.

The essentials for performing a good forceps operation are — ability to make an accurate diagnosis of position, familiarity with the mechanism of labor, deliberation in grasping and extracting the head.

Clinical Department.

MASSACHUSETTS GENERAL HOSPITAL.

Clinical Meeting of the Staff, Held at the Treadwell Library, Dec. 12, 1903.

Dr. H. H. A. Beach in the chair.

A CASE OF HYSTERIA.

BY H. C. BALDWIN, M.D.

Up to the age of nineteen Miss M., who is now thirty-eight, had been comparatively strong, and was able to walk and run as well as any one. She had never had fainting spells. She had no trouble with her voice. She had done everything like anybody else.

The winter previous had had some pain in her back. One day when her sister put her hand unexpectedly on the patient's back, the patient collapsed. The family doctor was called, and he put her to bed to rest for a week, telling the family that the patient's back would be well by that time. The patient did not get out of bed at all for three years, and was not even able to be lifted into a reclining chair during this time. After she had been in bed six months, she lost absolutely the power of the right leg, and it became perfectly numb, so that she did not feel when a pin was stuck in it. She also had numbness and paralysis of the right arm. The severe pain in her back continued. For a time she ran a continuous low fever, which ended up with a severe attack of malaria. The numbness continued in the right leg and arm for about a year. She recovered the use of the arm perfectly, but she has never moved the leg since.

She was taken to Philadelphia after she had been in bed three years, and remained there for six months in a private sanatorium, where she was under the care of eminent doctors. She was out of bed but very little for five years, and then began to go round a little with crutches. Her left leg was all right, but her right leg was perfectly useless. She could neither move it nor bear any weight upon it. About four months after she began to get round, she lost her balance and fell down a flight of stairs, striking the back of her head. She was not unconscious, but after falling downstairs, she was in bed for four months. For a long period after this accident she was unable to make any sound at all, and since that time until she came under my care — a period of over thirteen years — she has never been able to speak above a low whisper. Before getting out of bed at all, she was fitted to a brace, and she has worn this brace constantly ever since, and for the last five years, both day and night, until I took it off in October of this year.

The patient came to see me at my office Sept. 16, 1903. Physical examination showed lively reflexes — right and left. There was no marked wasting of the right leg, but the muscles were soft and the joints were apparently relaxed. There was marked toe-drop. Dr. Goldthwait examined her back, and reported there was no trouble with the back. Dr. Goodale examined her throat and reported that there was no trouble with the vocal cords. Through the courtesy of Dr. Minot and Dr. Shattuck I have been allowed to have the care of her while she has been a patient in their wards in the hospital.

I told her that I could teach her to talk by developing head tones in the same way that music teachers develop voices in pupils who have no voices. The usual methods of getting a patient with functional aphonia to speak were of no avail in this case, and the voice has been developed gradually by systematic daily practice. It was a period of two months before the speaking voice was natural and before the patient could talk out loud without concentrating her whole attention on her voice.

The developing of the use of the right leg has been a much more difficult matter. A plaster bandage was put on the knee at first, and the patient was told that the plaster would keep the knee from buckling, and that she would be able to push her leg along. It was at least six weeks before the patient could move her toes the slightest, but she was daily made to stand and to work at walking, her right leg being pushed along while she was held by the nurse and myself. The most difficult task has been to teach her to balance. She had completely lost all power of balancing, and has been much more difficult to teach than a child.

Her brace was removed the last of October, and for a week the patient was most unhappy. Within the last month she has learned to make every motion of her right leg; she can stand alone; she can walk a little alone, and with the aid of a cane can get about pretty well. Yesterday she went up and down a flight of sixteen steps alone.

THYROIDECTOMY FOR EXOPHTHALMIC GOITER.

BY JAMES MARSH JACKSON, M.D.

The first case which I wish to show is the patient with exophthalmic goiter on whom Professor Mikulicz performed thyroidectomy last summer. She first came to the Out-Patient Department Oct. 2, 1901, and was under medical treatment for some time without deriving material benefit. (She is not included in the series of cases treated by bromide of quinine.) The prominent symptoms before operation were exophthalmos, large goiter of both lobes (especially the left) tachycardia (140), tremor, sweating, diarrhea (four to eight movements a day), nervousness and irritability of temper, hoarseness and inability to stay in a hot room.

Examination at that time showed marked prominence of the eyes, but no Stellwag sign. Von Graefe's sign was present. She was able to wrinkle the forehead slightly, and convergence of the eyes was normal. Examination of the throat showed no paralysis of the recurrent laryngeal. The hands were moist and warm; there was marked sweating of the body and considerable tremor of the hands and tongue. The heart was enlarged slightly to the left; first sound at apex loud; second weak; no murmurs. Patient was unable to work, and was sent into the hospital for rest and treatment. Operation was performed by Professor Mikulicz on May 20, 1903. The left lobe of the thyroid was extirpated as a whole and the superior and inferior thyroid arteries were tied, stopping completely the pulsation of the right lobe. For ten days she ran a slight temperature, 99° to 101.5° F., and the pulse 130 and 140 at first, gradually diminished until on the tenth day it was reduced to 68. No change in respiration noted. Recovery otherwise

uneventful. Since operation the following changes have occurred: In the first place the patient feels much better, and has been able to work continuously since leaving the hospital. The pulse rate, according to the records of the Out-Patient Department, has never been above 84, whereas you will remember formerly it was rarely under 130. The heart has diminished in size and is now normal. Eyes: Patient thinks that her eyes were much less prominent after the operation. Von Graefe's sign is now absent. Tremor is less marked but still present. She has gained thirteen and three-fourths pounds since operation. Now has no diarrhea. There has been no change in sweating since the operation; it is still very marked. Irritability of temper decidedly worse since the operation. Now sleeps well, though previously was considerably troubled with insomnia. Headache has been more marked since operation. Hoarseness remains the same. Had a short, hacking cough before operation, none since. Polyuria has been a marked symptom from the beginning, and no change was effected by operation.

Of late patient has noticed that the right lobe of the thyroid has been increasing in size and that the eyes are becoming more prominent. She says, also, that the cough, which has been absent since May, has again returned and is about the same as it was prior to operation. In conclusion I wish to draw attention to the marked improvement which has taken place in her general condition and the particular symptoms of exophthalmos, pulse rate, tremor, diarrhea, insomnia and cough, whereas the following symptoms are either not improved or slightly worse: perspiration, irritability of temper, headache, hoarseness and polyuria. I have recently started her on bromide of quinine, five grains three times a day, and shall watch the effect of this before considering the advisability of another operation.

OBSTRUCTION OF THE SUPERIOR VENA CAVA.

Mrs. M. S., aged thirty-five, married.

Family history: Mother died of heart disease, otherwise negative. Past history: Has always been well and strong, and has borne two children, the last three years ago.

Present illness. On Oct. 22, 1903, patient came to the Out-Patient Department of the Massachusetts General Hospital, complaining that for the past three years she has had more or less shortness of breath, smothering sensation, attacks of palpitation, rush of blood to the head, loss of strength and pain under the sternum. These symptoms have been growing worse of late, and she is now seriously inconvenienced in her work. A year ago, she says, a lump appeared over the right parietal bone, which increased gradually in size until it became as large as an egg. Her doctor incised this, but found no pus, there being only a discharge of dark blood. She was given some medicine, the nature of which she does not know, and the tumor disappeared. This is, of course, suggestive of gumma. Examination of the chest shows a marked dilatation of the superficial veins from mid-sternum to umbilicus. The heart is normal in size and nothing abnormal is made out by auscultation. Percussion over the upper border of the sternum gives a sense of resistance over an area about the size of a silver dollar. The x-ray plate shows a broadening of the upper part of the cardiac shadow. The probability is that we have here a tumor pressing on the superior vena cava in the mediastinum, and as there is a possibility that this is a gumma, she has been given iodide of potash and mercury. As yet no change has been noted from the treatment.

Medical Progress.

RECENT PROGRESS IN LARYNGOLOGY.

BY A. COOLIDGE, JR., M.D., BOSTON.

HAY FEVER ANTITOXIN.

THE recent work of Dunbar[1] of Hamburg in separating a toxin from the pollen of different grasses, from which he has produced an antitoxin for hay fever, may be justly called the most striking laryngological novelty of the year. The author was led to the supposition that flowering grasses had a causative relation to hay fever. By carefully collecting the pollen of different gramineæ he found that when some of this pollen is brought in contact with the conjunctiva or nasal mucous membrane or any other mucous membrane of a hay-fever patient, an itching, tickling and burning will be produced, followed by a vascular injection, swelling and excessive secretion, whereas it is inert in persons who do not suffer from hay fever. The experiments showed great variations in the sensitiveness of different hay-fever patients toward the pollen; it is, however, present in all cases, and the accompanying symptoms correspond to the symptoms observed in many patients in natural hay fever. It is possible that there are persons who do not react to the pollen of grasses, but to pollen of other plants in a similar manner. It is true that some persons suffer from nervous coryza who do not react to the pollen granules of the gramineæ, but the author suggests that the term "hay fever" should be used only in such cases as react. The results of experiments led him to the conclusion that grass pollen granules contain the exciting agent of the disease called hay fever, which is differentiated from other similar affections essentially by the fact that it appears only at one period of the year. The positive conclusion of the causative effect of pollen granules in the production of hay fever led to the inquiry into the chemical or mechanical action of these bodies. The pollen granules of grasses found active had without exception a smooth surface. Products obtained from the pollen granules by the action of alcohol or ether had no specific effect upon hay-fever patients. The pollen granules retained their specific action in full force after the extraction of these substances. The pollen of the gramineæ differs from the pollen of other plants in containing starch granules which entirely fill the body of the pollen. When immersed in water the starch bodies of the pollen appear as rods. When immersed in salt solution these rods often remain unaffected, but when immersed in secretions of mucous membrane, in lachrymal, in nasal or salivary secretions or in blood serum and kept at body heat these starch rods will soon begin to dissolve. If at the moment of complete solution the undissolved portion be separated by centrifugal process, it will be found that it is inert in its effects.

[1] Berl. klin. Woch., 1903, 24, 25, 26. English translation by Joachim, Annals Otol., Rhin. and Laryngol., September.

With the solution hay fever can be produced. The iodine reaction of the starch rods is somewhat atypical, this suggesting a double product containing besides starch an albuminous substance. This albuminous substance was extracted from the pulverized pollen. It reacts to all tests for albumen, contains the entire hay-fever poison, and it is possible to extract it so completely from the pollen granules that the residue is inert. The protein obtained is extremely poisonous to hay-fever patients. After establishing the fact that the pollen of grasses contained the hay-fever poison, experiments were at once begun to obtain a specific antitoxin. It became evident that animals of the same kind differed remarkably in their resistance to the hay-fever poison. Of the horses treated some reacted but feebly to the toxin, others not at all. One horse of blooded stock reacted so violently to a much smaller dose than had been well borne by goats that for days it was doubtful if he would survive. Several horses have been found reacting to the pollen toxin. These when injected with 4 gr. of pollen granules, or with the toxin derived from this amount of pollen, began soon after the subcutaneous injection to show symptoms of disturbance, loss of appetite, muscular twitching, urticaria, rise of temperature. In the blood of susceptible horses antitoxic properties could be discovered after four weeks, four injections having been administered. If a drop of the toxin solution containing $\frac{1}{40}$ mgm. of the protein, which produces severe reactive symptoms in hay-fever patients, be mixed with a drop of the horse serum possessing antitoxic action, it will be found that this mixture, when applied to the mucous membrane of hay-fever patients is no longer productive of irritative reaction. In the course of a few months this antitoxin reaction increases many times. With this serum it is possible to neutralize the pollen toxin as well as to subdue a reactive inflammation previously produced by the application of pollen toxin to mucous membranes of hay-fever patients; larger doses of antitoxin are necessary to overcome already existing irritations than are needed for immediate neutralization of the poison. As a result of the report of cases in which the serum has been used by patients habitually subject to hay fever, the author concludes that a careful prophylactic use of the serum, or its use as soon as the first symptoms of irritation appear, will bring about a surer result, and with a smaller amount of serum, than when used after a severe attack. The use of antitoxin externally is preferable to the subcutaneous use, if it should prove efficient in the control of asthma; subcutaneously antitoxin is entirely inert on normal human beings, while on hay-fever subjects it gives rise to disagreeable symptoms of irritation.

OPERATIONS UPON THE ACCESSORY SINUSES.

For the last few years the surgery of the accessory sinuses has been a subject of especial study, to which Luc has contributed in no small degree. During his recent visit to this country at the time of the Medical Congress in Washington, Luc presented a paper summarizing his present opinions on the radical treatment of chronic suppurations of these cavities.[2] In regard to the maxillary antrum he believes that it is not advisable to adopt the radical operation in any case of chronic abscess without having previously attempted to cure it by washings of the diseased cavity, after a puncture through the inferior meatus. In the radical, commonly known as the Caldwell-Luc operation, after making a wide opening through the canine fossa and cleaning the cavity, an opening is made at the expense of the internal or nasal wall of the sinus, in order to create a wide and permanent communication between the antrum and the nasal fossa. This resection, which requires simultaneous ablation of the greater part of the middle and inferior turbinals, is greatly facilitated by the introduction of the little finger into the nostril. The antro-nasal communication must be a large and permanent one, whereas the antro-buccal one is to last only as long as it is necessary for cleaning and curetting the cavity.

In regard to the frontal sinus the author has found that the so called Ogston-Luc operation has its limitations, and after reviewing the more radical operations of Kuhnt and Jansen, recommends the method of Killian, which is a sort of combination of all three. It implies the immediate closing of the wound and the subsequent drainage by the nose, and it opens the floor of the sinus. It removes the greater part of the anterior wall, but it preserves a bony bridge corresponding to the orbital arcade, which greatly lessens the deformity. He regards this operation as being at present the surest and safest method for radical cure of chronic frontal suppurations in cases made difficult by abnormal dimensions of the cavity and especially by its extension to the temporal region, whereas the Ogston-Luc method, which is easier for the surgeon and less disfiguring to the patient, finds its ideal application in patients with a small sinus.

The most interesting part of the paper is that relating to the ethmoid cells. The middle and even the posterior cells, including the sphenoidal cavity, which may be considered as the most remote of them, are within reach of our eyes and our instruments, but the anterior cells that line the naso-frontal outlet will always escape unless we make a previous resection of bone. A result of experience has been to abandon the use of nasal curettes. He uses a special forceps, whose blades are large enough to seize much at a time and flat enough to be easily thrust into the recesses of the middle meatus. If the nasal fossa is filled with polypi they are removed by means of the cold snare. Under cocaine the middle turbinal is first attacked with the largest flat forceps, squeezing bone, mucosa and polypi, tearing them off with

[2] Trans. Amer. Laryngol. Asso., 1903.

a rapid twisting movement. After checking the hemorrhage with gauze, any myxomatous mass or bony trabeculæ met by the forceps are to be seized till the instrument finds no other resistance than that of the bony walls limiting the nasal cavity. The only wall which the author has involuntarily opened is the anterior wall of the sphenoidal sinus. The method when applied to the ethmoidal suppuration complicating a frontal maxillary empyema can but be considered as a preliminary step to the radical operation for the latter disease, since the Caldwell-Luc as well as the Killian method affords the surgeon every facility for the opening and curetting of the neighboring cells.

The sphenoidal cavity, in a case of chronic empyema, may be approached either through the nose or through the maxillary antrum. When the only difficulty in getting at the sphenoidal front wall is the middle turbinal and the posterior ethmoid cells there can be no simpler method for reaching and opening the sinus than the one described for curetting the ethmoid cells. In case of abnormal resistance of the anterior wall it might be advisable to use a perforator. The coincidence of an antrum empyema with the sphenoidal suppuration makes the antral passage to the sphenoidal sinus the proper one, as being both easier and safer. A resection of the anterior and internal walls of the antrum opens a direct and simple route, which should be chosen even through a normal antrum, if the passage through the nasal cavity is obstructed.

OPERATION FOR DEFLECTED SEPTUM.

Although different operations and modifications of operations for the straightening of deflected septa have increased each year, we seem to be as far as ever from universally accepted methods. The problems are so varied that general rules are difficult. As a result of study and experience Douglass [3] concludes that the theory that the forceps by twisting and bending break the septal cartilage into several fragments enclosed in a layer of mucous membrane is fallacious. What appears to be a lessened elasticity of this cartilage after use of forceps is in almost every case the result either of the incision through the cartilage or its separation from the bony septum. When sections are made of the fractured septum some time after healing it is not found that there has been any attempt at the production of a new cartilaginous tissue. The displaced fragments remain separate, and connective tissue has been formed uniting these fragments. The only way of dealing with the fibrous bands of tissue formed along the line of fracture is by incision, and these incisions should be as few as possible. Incisions intended to correct septal deflections should be made along the entire length of the triangular cartilage. The greatest fallacy in septal work is the belief that it is necessary to make many incisions, especially the crucial incision. Every angle from a cross incision increases the tendency to displacement of the fragments and leaves a tendency to perforation.

An important point is the recognition of the part played by the superior maxillary spine. This spine receives anteriorly the triangular cartilage and posteriorly the anterior edge of the vomer. The septum may be incised, the forceps may break the triangular cartilage from its attachment, the vomer may be fractured and separated from the superior maxillary ridge, but if the cartilage is not separated from the superior maxillary spine the result in many cases will not be good. The relation of the septum to the superior maxillary spine is somewhat analogous to the main sheet of a sail. If this is cut the septum will be found freely mobile and can be placed and retained as desired. So important is this spine that when it has been completely severed it is often unnecessary to make any cut in the septum or to use forceps to break the septum from the ethmoid. After anesthesia the spine may be cut either through the lip or nose. In the former case the lip is raised and the knife plunged to the right or left of the raphe; the chisel is introduced and one finger placed in the nostril to determine the position of the chisel and the spine; the chisel is then gently forced through the bone by light blows. In operating through the nose the incision is made just behind the vestibule on the floor of the nose, where it joins the septum, and the spine is cut by the chisel as before.

PARAFFIN INJECTION.

A review of the reports on the injection of paraffin in addition to his own observations and experiments with animals leads Schleifstein [4] to the following conclusions: Both the harder form of paraffin and that which melts at a lower temperature is well borne by animal tissues. If the skin into which it is injected is too tense there may be destruction of the hair follicles, with loss of the hair, and also the wound made by the needle may not properly heal, or there may be even a sloughing from pressure. This is dependent upon tension and not upon the kind of paraffin used. The injected paraffin is in time penetrated by compact connective tissue, which beyond increasing its bulk does not affect it. Hard paraffin which melts at a high temperature has no special disadvantages and is less liable to give trouble in case the temperature of the body rises. In parts of the body where it is not under accurate control during injection the hardest paraffin should be used, as it is less likely to reach undesired spots and to cause trouble. In cases where the injection may be considered curative it may be used without hesitation, but where its use is purely cosmetic it is not yet possible to be perfectly sure of results. There is sometimes an unexpected development, and the operator should be sure that the patient understands the situation and expresses a wish that it should be tried.

TREATMENT OF ATROPHIC RHINITIS WITH MUCIN.

A report of advanced cases of atrophic rhinitis treated with mucin is given by Stuart Low.[5] The results are distinctly good. The mucin is given both internally and locally. A solution is made by rubbing up one tabloid and one "soloid" of mucin in 2 dr. of warm lime water and 6 of sterilized water. This solution may be used as a spray. At the beginning of the treatment the patient should be seen daily for a week, and the mucous membrane of the nose cleaned and massaged with mucin solution. The patient is at first to syringe with the solution twice a day, but soon need do so at night only. Internally eight to twelve mucin tabloids are taken daily, both before and after meals. This treatment improves the digestion as well as the local trouble. The solution as given above for local use may be found painful for the patient, in which case it should be diluted.

TREATMENT OF LUPUS OF THE RESPIRATORY MUCOUS MEMBRANE.

Christiansen, in a report to the Danish Oto-Laryngological Association of Copenhagen,[6] states that three-fourths of the patients who apply to the Finsen Light Institute for treatment for lupus of the skin are found to have it also of the mucous membrane. The mucous affection has generally been primary. Lupus is most frequently situated in the foremost part of the nasal cavity, the septum and the vestibule, then on the lips and upper gum. The nodules appear as dark red spots upon a lighter red background; there are also often miliary tubercles and ulcerations. The disease requires a very energetic local treatment. Wherever possible the light is applied as to the skin, by "compress glasses," and is focused upon the spot. The reaction appears as a hyperemia in severe cases with a loss of epithelium, but never as a bulla. The results are almost as good as in the treatment of the skin disease. When the disease is situated where it cannot be reached by the light, the nodule is punctured with the galvano-cautery, care being taken not to burn anything except the nodule. Solutions of iodine, corrosive sublimate 1–1000 and permanganate of potash 1–700 are also used. The use of lactic acid has been found to be valueless. The patient is seen daily and the surface kept free from crusts. For the details of treatment, both with and without the light, the reader is referred to the fuller report.

(To be continued)

Reports of Societies.

BOSTON SOCIETY OF PSYCHIATRY AND NEUROLOGY.[1]

J. W. COURTNEY, M.D., SECRETARY.

REGULAR meeting Thursday, Oct. 15, 1903, DR. G. L. WALTON in the chair.

[5] Journ. Laryngol., Rhin. & Otol., April, 1903.
[6] Ibid., October.
[1] The following discussion was received too late for publication with Dr. G. L. Walton's paper. See JOURNAL, Jan. 21, p. 61, 1904.

ORAL COMMUNICATIONS.

DR. E. W. TAYLOR: I have three specimens to present, with brief reference to the clinical histories.

POTT'S DISEASE.

The first is an unusually striking case of Pott's disease occurring in an adult. The patient, a man of forty-five, was taken with typhoid fever. Three weeks after the onset of the typhoid fever he developed Pott's disease. What relation the Pott's disease has to typhoid fever I am not able to state. He was admitted to the Long Island Hospital, and became paraplegic with a large kyphosis in the dorso-lumbar region. During his stay he grew continually worse. Operation was considered, but not attempted. He was transferred to the Carney Hospital, under Dr. Goldthwait's care, who, by assiduous treatment, was able to bring the man to his feet; he later returned to the Long Island Hospital, and died of generalized tuberculosis, particularly of the genito-urinary tract. The autopsy was done by Dr. Magrath, and I present a vertical section made through the spinal column which illustrates extremely well the method by which compression of the cord takes place in Pott's disease associated with paraplegia. You will see on the dorsal surface of the body of the vertebra a tuberculous deposit which has gradually encroached upon the spinal cord, forming a kyphosis at this point which is, in the specimen, not particularly apparent. One body is practically eroded. The cord is pressed upon and virtually destroyed at this point.

DEFECTIVE CEREBRAL DEVELOPMENT.

The other cases I have to report are both instances of defective cerebral development. The first is from the Massachusetts School for Feeble Minded. The brain is extremely interesting, because it shows a tendency to simplification as a whole, without any definite defect in any particular portion. This brain, if presented to any of us, I think, might be regarded as the brain of one of the lower mammalia. The cerebellum extends out behind, the convolutions are small, and yet the brain as a whole shows a very perfect development. This came from an idiot child of four, of Italian parentage, as I remember it, of very feeble mental development; one, I think, of several in the same family. This is a striking and, so far as my knowledge goes, unusual type of brain defect.

The third case is a still more remarkable one in many ways, coming from a child of six, for several years an inmate of Long Island Hospital, suffering from infantile cerebral paralysis. This child was born, I think, of healthy parents. At a very early age he began to show spastic symptoms, and the legs were drawn up and contracted. The development of the child mentally and physically was very much retarded, and for several years he lay at the hospital helpless and apparently hopelessly so. The condition of the brain, however, could not

have been suspected from the clinical phenomena. The more we study these cases the more we find it is impossible to predict what the condition of the brain is going to be, from the clinical phenomena during life. The hemispheres are present but the convolutions are highly defective. On one side is a cyst which is not common. There is a large opening in the occipital lobe which connects with the dilated ventricle. The autopsy was done by Dr. Magrath, and at the time of the autopsy this defect was closed over by membrane which was probably the pia.

DISCUSSION.

DR. G. B. MAGRATH: I remember very well indeed the case to which Dr. Taylor has just referred and the statement as to what the covering-in membrane of this depression was. The opening which existed in that part of the hemisphere was covered in the fresh state by a very thin layer of pia. It was intact at the time of the removal of the calvarium, but was continuous with the remainder of the pia.

SPINAL SYMPTOMS OF BROWN-SEQUARD TYPE.

DR. G. L. WALTON mentioned a case with rather baffling symptoms pointing to the spinal cord. A woman of middle age gave a history of having fallen down a flight of stairs six months ago, after which swelling of the legs appeared and pain in the back, with gradual progressive loss of power and sensation in the lower extremities. It seemed also that after a previous accident she had lost power and had more or less pain. The whole course of the case seemed to show that irrespective of the accidents the whole trouble was a gradually progressive one. There had been one miscarriage, and though no definite specific history was made out, large doses of iodide of potassium were given, in view of the possibility of specific meningomyelitis, but with no result. She now requires morphia for the pain. In view of this history and the patient's desire to have something tried, Dr. Warren will make an exploratory operation in the hope of finding a tumor. The distribution of the paralysis is of an incomplete Brown-Sequard variety, namely, complete loss of power in the left leg, with partial loss of power in the right, loss of pain and temperature sense on the right up to the groin, and loss of muscle sense on both sides. There is an area of hyperesthesia in the right flank and over the left lower ribs. There is exaggeration of the knee jerk and a Babinski on both sides; ankle clonus on the left. The tenth dorsal lamina will first be removed, and operation extended upward if nothing is found at that point. (At the next meeting Dr. Walton reported that although several laminæ were removed and the exploration extended further by the probe, nothing abnormal appeared beyond an unusual spurt of clear fluid upon opening the dura. The cord appeared of normal size, color and consistency. No ill effects followed the operation. There had been slight improvement in the paralysis but no relief of pain.)

DISCUSSION.

DR. P. C. KNAPP: In specific meningomyelitis I have not noticed such striking hyperesthesia as noted in this case, which is more suggestive of something malignant. I have seen such hyperesthesia with malignant disease of the vertebræ.

OBSTETRICAL PALSY: OPERATION.

DR. J. W. COURTNEY: I have here a small boy whom I want to show, not because of the nature of the case, but on account of the ingenious surgical measure that was devised by Drs. Cumston and Cotton for the purpose of relief. The case is an unusually severe one of obstetrical palsy, resulting in a flail-like condition of the right arm. When I first examined the boy, some months ago, I found the extensors of the hand to be the only muscles capable of function. I found also that these muscles had retained their faradic irritability. Now, as extension of the hand was of no practical use to the boy, the surgeons cut nearly all the tendons about the wrist, thrust the upper ends of the severed extensors between the bones of the forearm to its anterior surface, and there sewed them to the lower ends of the flexors. Union was obviously successful, for the boy is now beginning to grasp objects, although with little power as yet. I think, however, that with time his power will grow in this respect.

In connection with this case it is interesting historically to note, although it has no bearing on the boy's condition, that his maternal great-great-grandmother and great-grandmother had goiter, that his maternal grandmother and uncle now have enormous goiters, and that his own mother is developing that disease.

DR. GEORGE L. WALTON read a paper entitled,

THE PREVAILING CONCEPTION OF DEGENERACY AND DEGENERATE, WITH A PLEA FOR INTRODUCING THE SUPPLEMENTARY TERMS, DEVIATION AND DEVIATE.

DISCUSSION.

DR. WALTER CHANNING: I don't know very much about "superior" degenerates. That expression is more or less recent. I have had something to do at times with inferior ones. I fully agree with what the reader has said, and I should certainly approve using either the expression he suggests or some other one in a good many cases where we make use of the ordinary ones of degeneracy or the stigmata of degeneration. I suppose a man like Nordau is largely responsible for the prevalent use of these expressions. There is a popular and scientific way of using them, and I don't know what we can do to interfere with the popular use, but it seems to me scientifically we can do a great deal. It is hard to know what a real stigma of degeneracy is. Many of us have adopted views in regard to the palate, but from recent investigations I have made I

have come more and more to the conclusion that we have so far had very little accurate information about the shape or development or significance of slight deformities of the palate. The results that I have obtained during the last year in regard to the palate corroborate those I have obtained before. There has not been any standard of comparison in estimating what a normal palate should be, except in a very empirical way. During the last year I have had made at the American Museum of Natural History, at New York, under the direction of Dr. Boaz, all the casts of palates I have, and all the casts of school children, the length, width and height measured, and I have had constructed from those measurements what would be regarded as an average palate for a normal school child from the age of six to thirteen. This has not been done before, as far as I know, with regard to the palate. We have constant reference by writers to the significance of slight aberration of the palate. In regard to the palate of the adult we have not any standard of comparison; we do not know what an average palate of the adult is. I had taken, last year, some 200 casts of normal adults to find out what may be a standard of comparison. It is so with regard to many other stigmata of degeneration. We have no standard of comparison, and the observations are of very little value. I am willing to adopt the suggestions of Dr. Walton and do all that is in my power to make the use of the word degeneration less common and less unscientific.

Dr. C. F. Folsom: I have very little to say. I agree with Dr. Walton. When I was in London, about twenty years ago, some of my friends were interested in this subject, and had been for a number of years getting a fashionable hatmaker in London to preserve unusual forms of heads with the names of the people to whom they belonged. The series has never been published and never used except in private. There was every deviation in the form of the skull which Nordau and Lombroso would class as degeneracy, and yet the men were not men who in any sense of the word could be called degenerates. The term degeneration was used by the writers in Morel's time, and most of us are familiar with his classical work in which the term is used with reference to individuals who have reverted to a lower type or to a distant ancestral type and so inferior that one could not fail to recognize them. The term has been widened until, in Nordau's time, Byron and Tolstoi are called degenerates. Dr. Walton's distinction, it seems to me, is an exceedingly important one and important in many ways. In a medico-legal way alienists are very apt to be satisfied in classing a criminal as a degenerate, and when they label him as a degenerate they call him irresponsible, and there is a great deal of confusion of terms and a very uncertain and unscientific classification of criminals. The difficulty Dr. Channing speaks of is practical, and that is, of estimating standards. If we adopt Dr. Walton's term it is not necessary to adopt any standard, because we do not commit ourselves to any theory with regard to capacity or responsibility or anything of the sort in using the word deviate. In using the word degeneration for these individuals who are not in any proper sense degenerates but simply deviates from the ordinary type, we carry with it a sense that degeneration involves lack of capacity, judgment, self-control and self-management, which is a far different case.

Mr. Walter Soren: Really, the only reason why I was asked to come to this meeting was because Dr. Walton feared that the medical brethren might severely attack his paper, and he wanted the support of some layman of whom he could make sure in advance. I have long had the feeling, expressed by Dr. Walton and others, that the public has been led to associate an evil meaning with the terms degenerate and degeneracy. Those of us who are so unfortunate as to dabble in criminology constantly run across it; and it may be that criminologists are primarily responsible for the association in the public mind of moral delinquency with these terms. How inseparable the meaning of wrongdoing is from the word degenerate is frequently apparent in the trials of criminal cases. In the popular estimation a degenerate is synonymous with an unregenerate. For this reason alone, aside from the desirability of a more precise scientific classification, the substitute proposed by Dr. Walton would be very welcome. It would be very helpful to work I am interested in if his suggestion were adopted, and the public became impressed with the idea that a degenerate or deviate is not necessarily a moral delinquent.

Dr. Woods: It struck me that Dr. Walton's new word "deviate" is a very good expression, inasmuch as deviation is to be expected in all attributes, whether physical or mental. If we measure the physical characteristics of mankind — stature or strength, for example — and arrange the measurments in a series, we find that they fall on either side of a common center or mean. As far as investigations have gone into the measurements of mental traits — such, for instance, as Francis Galton has made — it appears that similiar deviations occur. Thus the term "deviate" carries with it the idea that we have something to be expected from the theory of chances. Degeneration, on the other hand, implies something associated with moral baseness, weakness or disease. So it seems to me the term is a very good one, as it provides for a much-needed distinction.

Dr. J. J. Putnam: I have been very much interested in Dr. Walton's paper, and I should entirely agree with him that the condition has become intolerable with regard to the use of the word degeneration. At the same time it certainly has been of a great deal of use in stimulating observation and discussion. I should think the only question in regard to the substitution of the terms deviation and deviate would be whether they really mean enough. As a matter of fact the normal condition is a devia-

tion; in other words, there is no normal. Every individual is a bundle of qualities. There is no normal, and if the people get to using freely the terms deviation and deviate there will soon be no pretence at a norm; everything will be "deviation." We might be stimulated to study slight peculiarities, and the term might lose its meaning and dignity through abuse. On the other hand I believe that the proper popularization of the term deserves encouragement.

(To be continued.)

Recent Literature.

A Textbook of the Practice of Medicine. By JAMES M. ANDERS, M.D., Ph.D., LL.D., Professor of the Practice of Medicine and of Clinical Medicine, Medico-Chirurgical College, Philadelphia. Sixth edition, thoroughly revised. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

The sixth edition of this well-known textbook on the practice of medicine contains 1,295 pages. Although much of the material which would naturally have been included in such a book fifteen or twenty years ago is omitted, a number of new subjects have been discussed, among which paratyphoid fever, trypanosomiasis, adiposis dolorosa and amaurotic family idiocy may be mentioned. We are a little surprised that the two latter affections have not found space in earlier editions. The general appearance of the book is as heretofore. We would especially commend two admirable colored plates on the parasite of malaria.

A Surgical Handbook. For the use of Students, Practitioners, House Surgeons and Dressers. By FRANCIS M. CAIRD, M.B., F.R.C.S. (Edin.), Assistant Surgeon, Royal Infirmary, Edinburgh, and CHARLES W. CATHCART, M. B., F.R.C.S. (Eng. and Edin.), Surgeon Royal Infirmary, Edinburgh. With very numerous illustrations. Twelfth edition. London: Charles Griffin & Co., Limited; Chicago: W. T. Keener & Co. 1903.

This little handbook has reached its twelfth edition. On looking it over, we find that the authors have kept the book up to the progress of surgery. The book considers case-taking, treatment of patients before and after operations, anesthetics, general and local, etc.; in fact, all that a surgical dresser needs before beginning a service in the hospital. Besides that, it has in a condensed form the general information that a practitioner would care to turn to in case of necessity. The cuts are very crude but expressive. It is a good book of reference in minor surgery.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, FEBRUARY 18, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

THE ANNUAL REPORT OF HARVARD UNIVERSITY, 1902-3.

THE annual report of Harvard presents, as usual, many data of much general interest, and instructive comments thereon, especially from the president of the university. He points out that the death-rate of the university is remarkably low, being only 4.7 in 1,000 for the 632 members of the governing boards and the university staff. Among the 4,261 students in the university there were 10 deaths, being only 2.34 in 1,000. These figures lead President Eliot to reflect:

"How great a reduction in the death-rate may be hoped for in civilized countries from the development of general intelligence, the progress of medical science, and particularly of preventive medicine, and the enforcement of wholesome conditions of life, may be inferred from a comparison of the above statistics with the following death-rates in 1900 of certain classes of males in the city of Boston:

Males	15–20 years	5.71	per 1000
,,	20–25 ,,	8.13	,, ,,
,,	25–30 ,,	9.79	,, ,,

"The members of Harvard University are more intelligent than the average of the population; with a few exceptions they take advantage of all existing medical knowledge and skill; and they live under more wholesome conditions than those of the people at large. Hence their low death-rate in comparison with that of average men of like ages."

On the other hand, the amount of sickness in some of the departments, and especially in the undergraduate department, as indicated by the

"sign-offs" given in at the department office, which are supposed to state the cause of absence from usual duties, was considerable. Moreover, there was an extraordinary difference in the amount of sickness in the various departments. The students in Harvard College seem to be sick nearly twice as much as the students in the Lawrence Scientific School; and, curiously enough, the special students in these two undergraduate departments are ill much less than the regular students. The students in the college are sick more than ten times as often as the students in the professional schools. The figures given are not taken very seriously and in all probability do not correspond with any real facts. "It is the opinion of the *Medical Visitor* that a large proportion of the 'sign-offs' of undergraduates are uncalled for. The real disease is what soldiers call 'malingering,' which is a moral and not a physical disorder." Attention has been called to this in a previous report.

The Stillman Infirmary was in use during the year 1902–3 for the first time, and is reported as having amply demonstrated its usefulness and the excellence of its appointments. Two hundred twenty-three cases were admitted, of which 146 were discharged well, 74 were discharged relieved. The private-room patients numbered 89 and the ward patients 134. Good progress has been made toward finding means of support for the infirmary, but much remains to be done.

President Eliot states that the exercises most used by the students are gymnasium exercises, lawn tennis, hand-ball and golf. The games in which the public is most interested — namely, football, baseball and rowing — are serviceable to much smaller numbers of students, no one of these three sports serving more than one-sixth of the total number of students who reported the exercises they used. The game which has been conducted at Cambridge with the least intelligence and success is football — except from a pecuniary point of view.

"The breaking up of college work for the individual student by frequent absences to play games at a distance from Cambridge is an evil which ought to be checked. It is a greater evil than formerly, now that intercollegiate games take place all the year round; that is, in winter as well as in spring and autumn."

The dean of the college reports that the tendency at Harvard at the present time to complete the work for the degree of Bachelor of Arts in three years is very strong. Of the class of 1903, with a membership of 381, no less than 146 men completed their academic work in three years. Of these men a few go into business, but by far the greater proportion carry on professional or graduate studies either at Harvard or at other universities. The president considers that, with the present rate of increase, it probably will not be long before the majority of each entering class will obtain the Bachelor's degree in three years. On the other hand, he points out that "the ages at which young men are taking the degrees of Master of Arts, Master of Science and Doctor of Philosophy at Harvard University are still deplorably high. A young man who has come steadily on through all the grades of his education ought to procure the degree of Master of Arts with ease by the time he is twenty-three years old. Of the 94 men who took that degree at Commencement, 1903, 12 were under twenty-three, 16 were twenty-three, and 66 were over twenty-three. Of these 66, 35 were over twenty-eight. The degree of Doctor of Philosophy ought to be easily taken by the age of twenty-five. Last June, of the 28 men who received the degree of Doctor of Philosophy, 2 were under twenty-five, 4 were twenty-five, and 22 were over twenty-five. More than half the candidates were over twenty-eight. These figures show how irregular, broken and often belated the higher education of young Americans in arts and sciences still is. The candidates for these degrees, as the dean of the Graduate School points out (p. 139), are often men who come to the university for a year or more of study after having been for several years engaged in active pursuits."

The year 1902–3 is reported as having been for the Medical School a very interesting, but financially a bad one. A considerable deficit is stated to have been due in part to the progressive reduction of the number of students caused by the requirement of a degree for admission. The plans and estimates for the new buildings of the school were completed, the contracts were signed and construction is now well under way. Moreover, transactions were concluded with the trustees of several hospitals for their occupancy of portions of the large tract of new land belonging to the school. One urgent need of the Medical School — a dormitory with a common-room and restaurant attached — has not yet been provided for. Although the number of students has temporarily diminished, the activity and variety in medical

and surgical research has increased. A tentative schedule has been adopted for an elective fourth year. The "block" system of instruction continues under trial.

The dean reports that "the comparison of scholarship attained by the different classes since the requirement of a degree for admission has been in force proves the wisdom of the step taken — so far as the qualifications of the future graduate are concerned.

"The increase in the number of men taking graduate courses was very marked, the receipts being double that of the previous year, and the number of graduates attending the courses showed an increase of 64%. The summer courses showed also a decided gain in the number of students and of the courses taken."

During the year no less than four professors in the Medical School resigned: Professor Draper of the Department of Legal Medicine, Professor Wadsworth of the Department of Ophthalmology, Professor Porter of the Department of Surgery and Professor Dexter of the Department of Anatomy.

The Dental School stands greatly in need of an endowment, and as it also has raised its standard of admission its ability to meet expenses from receipts is likely to be further curtailed.

THE ETIOLOGY AND PATHOGENESIS OF PANCREATIC LITHIASIS.

PANCREATIC lithiasis being far less frequent than the hepatic or urinary forms, statistics are wanting for this reason so that it is difficult to say whether or not calculi of the pancreas are more infrequent in the male or children than in the female, as is the case with biliary lithiasis. The time of life at which this affection appears and whether climate has any influence in its production are as yet unsettled questions, and all that can be said is that the pancreatic calculus often coincides with other lithiases in the same individual, and from this fact it is quite probable that it has the same etiology.

Pancreatic lithiasis consequently belongs to that vast group of affections united under the name of arthritism. In point of fact direct and homogenous heredity of lithiasis is infrequent, but one often notes the pathological antecedents of calculous subjects, such as gout, rheumatism, obesity, asthma, biliary or urinary lithiasis, certain chronic dermatoses, migraine or hemorrhoids. All these affections are associated, succeed or substitute each other in the same families or in the same subject with such frequency that a general cause has been attributed to them. This general cause is due to a permanent hereditary disturbance of nutrition, giving rise to tardy oxidation, delay in the nutritive changes and uricemia. A sedentary life and also an excessive amount of food appear to play the *rôle* of predisposing causes in the formation of pancreatic calculi. Perhaps one might also add a generalized arteriosclerosis.

The afferent cause of pancreatic lithiasis in no way differs from that of biliary calculi. The pathologically changed pancreatic structures without doubt also contribute to the precipitation of the salts contained in the pancreatic juice and thus tend to form foreign bodies.

The various changes which are the starting point of calculi formation are both external and internal. Among the former we would mention neoplasms compressing the pancreatic ducts, such as primary or secondary carcinoma, fibroids or cysts. The internal lesions are those producing stricture of the ducts either of an inflammatory or neoplastic nature. We could also add as a cause an obstruction of the canal of Wirsung at its distal end.

All these different conditions favor the precipitation of the pancreatic salts and finally give rise to the formation of stones in varying number and size, but which do not necessarily have a central nucleus, as do those arising in the urinary tract, or gall bladder.

Other causes of pancreatic lithiasis have been put forward; one of the principal ones being direct infection of the pancreatic ducts from the digestive tract, as is the case of the gall bladder, or infection of the vessels of the gland by toxins manufactured during one of the infectious diseases.

The experiments of Duclaux have shown that in a normal state the pancreatic juice is aseptic. Now should its chemical composition become altered or should its free exit become hindered from narrowing of the ducts, the pancreatic juice becomes changed; it has become an excellent soil for the development and growth of pyogenic bacteria. Its component salts are precipitated and are the starting point for the formation of more or less voluminous calculi.

The toxins elaborated during infectious diseases, typhoid fever among others, act in the same fashion; so also do foci of suppuration in the neighborhood of the pancreas. These are causes which, by producing epithelial or fibrous pancreatites, set up inflammatory processes in

the canaliculi and ducts of the gland, and these, by the various changes produced in the pancreatic juice, engender lithiasis. One may admit that, in the case of the pancreas, there is infection of the excretory ducts, an angiopancreatitis, just as there is an angiocholitis or pyelonephritis.

The question now arises, Is it microbic infection or the diathesis of the subject which dominates the pathogenesis of pancreatic lithiasis? An answer to this may be sought thus: If typhoid intestinal catarrh propagated to the bile ducts becomes a lithogenous catarrh, if, in other words, the bacillus of typhoid is capable of producing biliary lithiasis, the question relative to the pancreas is a settled one. It remains to establish what other bacteria play such a part, other than the specific agent of typhoid. It is quite possible for any bacteria pullulating in the mucus of the bile ducts and gall bladder to set up chemical changes leading to a deposit of the mineral constituents of the bile. Consequently biliary lithiasis results from the manner of penetration of bacteria into the ducts and gall bladder, their number and especially the composition of the mucus. Should the latter hypothesis express the reality, the soil would be more important than the seed; biliary lithiasis would no longer be an accidental phenomenon, but would remain the expression of a previous condition of the organism, of an hereditary or congenital modification *totius substantiæ*, a diathesis. Pancreatic lithiasis should not, we think, form an exception to the rule, since it belongs to the same pathological family.

A STUDY OF RINDERPEST IN THE PHILIPPINE ISLANDS.

A PRELIMINARY report on the study of rinderpest of cattle and carabao in the Philippine Islands from the Serum Laboratory of the Bureau of Government Laboratories, published under the auspices of the Department of the Interior, is at hand. This report from the pen of Dr. James W. Jobling, director of the laboratory, concerns itself particularly with information regarding the disease for the benefit of cattle shippers and breeders, giving the symptoms, means of prevention and treatment of the affection.

It appears that the disease, rinderpest, dates back almost to the Christian era, when an epidemic was described which bears a close resemblance to those later observed. Rinderpest has led to the death of several million cattle in Europe alone, the disease usually appearing in the form of epidemics. In 1708 the affection was prevalent in Russia, whence it spread to all parts of Europe, leading to an enormous death-rate among the cattle attacked. Apparently the disease first appeared in the Philippine Islands in 1882, and since then has extended to most of the islands of the archipelago, with a loss among cattle and carabao estimated by some as 90%.

The actual cause of the disease is not known, but by analogy it is fair to assume that a microörganism is ultimately responsible. Transmission is usually by infected ground rather than by atmosphere or running water. The danger apparently lies in careless disposition of the objects which have come in contact with sick animals. Carcasses of animals are also liable to spread the infection as well as the hides. The danger to cattle shippers lies in transporting animals in vessels which previously have been used in the transportation of diseased animals. Experimentally it has been shown that the injection of 0.1 cc. of blood from a sick animal is sufficient to reproduce the disease. In general, experience shows that if the precaution were general of isolating animals sick with the disease the danger of infection would be very greatly reduced.

The incubation period is from six to ten days. There is a preliminary rise of temperature; a disinclination on the part of the animal to take food; infection of mucous membrane of the eye, with a slight watery discharge; increased discharge of mucus from the nose; evidence of great thirst and general apathy. The animal ultimately becomes greatly prostrated, weaker and finally dies, with an increase of the symptoms noted, in a period of from two to ten days from the first rise of temperature. Postmortem the tissues show various forms of inflammatory change, together with distinct alterations in the intestinal tract. Peyer's patches are often enlarged, but apparently never ulcerated.

Practical suggestions are given in the pamphlet before us regarding measures of prevention, which consist essentially of complete isolation of the diseased animal, together with directions as to the disposal of animals dead of the disease. The hides, if preserved at all, should be thoroughly disinfected. Investigation is progressing regarding immunization by various methods, some of which are encouraging. Regarding immediate treatment, it may be said that up to the present time no treat-

ment has proved of any benefit when once an animal has contracted the disease. Various experiments made at the laboratory bear out this observation previously made by others. It is, therefore eminently desirable that prevention should be thorough and as complete as possible. In conclusion Dr. Jobling makes the following pertinent statement:

As no treatment has any effect upon the course of rinderpest, and as it has been proven that an animal which has been inoculated and has shown a good reaction seldom contracts the disease, it is evident that it is not only necessary to inoculate all the animals now in the Philippine Islands but also those to be imported. By this means it will be possible to completely remove rinderpest from the islands, but if such precautions are not taken, it will continue indefinitely, spreading from one point to another, killing off a large percentage of the young animals, and so working a continual hardship on the people.

We have no doubt that this disease will yield to the investigations which are now being made and which, no doubt, will be still more thoroughly carried out in the future.

ANTITOXIN: THE COST OF ITS PRODUCTION.

IN view of our statement (Jan. 28) "that under existing circumstances it would seem as if Massachusetts had no immediate reason to regret her arrangements for making her own serum," and in view of several articles which have recently appeared in different medical journals during the present season relative to the price of antitoxin as sold to consumers throughout the country, we have obtained from the Massachusetts Board of Health the following figures relative to the cost of production during the four years ended March 30, 1903. The production and output of diphtheria antitoxin depends largely upon the prevalence of diphtheria from year to year. For example, the total number of reported cases of diphtheria in Massachusetts in these four years was 36,604 and the mean annual number was consequently 9,151. The maximum number was 12,641, in 1900, and the minimum 7,134, in 1899. The number of bottles of antitoxin produced and distributed in the four years was 159,072, the maximum being 53,389 bottles, in 1900, and the minimum 31,997, in 1899, the average number distributed for each reported case being a little more than four bottles.

The statement that a considerable percentage of bottles is returned to private producers unused (to be replaced by them with a fresh product) applies equally to the State board's product, since unused packages are returned to the office of the board, after becoming inert in the hands of local boards of health. This fact would probably reduce the actual consumption per case to less than four bottles each.

The product produced and issued by the State board during those four years has been put up in small bottles, each containing 1,500 units of antitoxin, the quantity varying slightly from $3\frac{1}{4}$ to $4\frac{3}{4}$ cc., according to the strength of the product prepared. It has given uniform satisfaction to physicians and boards of health throughout the State, as to the quality of the product and the results obtained from its use. The cost of production during these four years was $31,543 for the 53,389 bottles, or 19.8 cents each. Since a package of this strength and size is not mentioned in the advertised statements of manufacturers, an exact comparison cannot be made. It is safe to call the retail price of a similar article at least $2.75, at which price the cost to the people of the State would not have been less than $437,438 for the four years. A saving of $405,905 was therefore effected to the commonwealth by this method of production. It is proper to say that the Board of Health enjoys some advantages for economical production which a commercial house would not have. The effect of this, however, upon the cost must be small.

MEDICAL NOTES.

SMALLPOX IN PHILADELPHIA. — Smallpox in Philadelphia is showing a tendency to decrease. There are still, however, each week a very considerable number of new cases, and deaths continue to occur. It has been ordered that visitors to the Philadelphia Hospital must either show satisfactory evidence of vaccination or else be vaccinated before entering the wards. Inmates must be vaccinated before visiting relatives in the city. These somewhat stringent measures are adopted to prevent the spread of the disease to the 5,000 inmates of the hospital.

DEATH OF DR. E. A. DE SCHWEINITZ. — Dr. E. A. de Schweinitz, chief of division in the Agricultural Department of the Government, died in Washington, Feb. 15. He was born in Salem, N. C., Jan. 18, 1866, and later was graduated from the University of North Carolina. He received the degree of Ph.D. from

Göttingen, and M.D. from Columbian University. He had attained a high rank as a chemist, and had published papers of value on bacteriological topics. For several years past he had been dean of the Medical Department of the Columbian University.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Feb. 17, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 41, scarlatina 28, typhoid fever 12, measles 240, smallpox 0.

Measles in Connecticut. — According to the monthly bulletin of the Connecticut State Board of Health, measles is prevailing as an epidemic in many towns of that state. Dr. Lindsley in his report considers the spread of the disease as in a measure due to a certain misunderstanding of the town regulation on the part of health officers. This regulation states that all cases of diphtheria and primary cases of measles shall be quarantined in such manner as the health officer may direct. Neglect of this rule has apparently led to the spread of the disease.

Annual Meeting. — The annual meeting of the Boston City Hospital Alumni Association was held on the 10th of February. The hospital was open to the graduates during the day, and a luncheon was given by the trustees at one o'clock.

The business meeting was held at Young's Hotel at six o'clock and at seven one hundred and twenty-four men sat down to dinner. Dr. Charles P. Bancroft of Concord, N. H., presided.

Speeches were made by Dr. Francis S. Watson, who spoke very beautifully of the late Dr. William Ingalls, for many years a surgeon to the hospital; Mr. Edmund Codman for the trustees; Mr. Moses of the New Hampshire Forestry Commission; Mr. Lyford, naval officer of the Port of Boston; Mr. Leach, president of the Brown Alumni; Dr. John G. Blake and Dr. Cheever. Dr. Paul Thorndike and Dr. J. Bapst Blake delighted the alumni with a humorous song.

Copies of a new catalogue were given to the members.

NEW YORK.

Address on Pancreatic Disease. — In assuming the duties of president of the Medical Association of the Greater City of New York Dr. Thomas E. Satterthwaite delivered an address, the greater portion of which was devoted to a consideration of pancreatic diseases and their treatment. This was by way of introduction to a general discussion on this subject, which was participated in by Drs. John C. Hemmeter of the University of Maryland, Richard M. Pearce of the Albany Medical College, George P. Müller of the University of Pennsylvania, Charles G. Stockton of the University of Buffalo, Glentworth R. Butler of Brooklyn and John B. Deaver of Philadelphia.

College of Pharmacy and Columbia University. — Arrangements have been made, subject to the approval of the college authorities, for uniting the New York College of Pharmacy with Columbia University. Nicholas Murray Butler, president of Columbia, has been nominated as president of the college by the trustees of that institution, and Prof. Charles F. Chandler, now president of the college, as first vice-president. Several years ago proposals by the College of Pharmacy to unite with Columbia had no result, but recently the university has determined that some provision for the teaching of pharmacy must be made in its educational system. The nominations for second and third vice-presidents respectively are William Jay Schieffelin and Herbert D. Robbins, both well-known members of large manufacturing drug houses.

A Tribute to Dr. Darlington. — In his address, on Feb. 8, on retiring from the presidency of the Medical Association of the Greater City of New York, Dr. Andrew H. Smith referred to the appointment of Dr. Darlington (one of the charter members of the association) as president of the board of health in the following words: "For the first time since its organization the health department has a medical man at its head. The insanity of our lawmakers, that in express terms forbade that this should ever be the case, experienced a lucid interval at the moment when the new city charter was under revision, and now at last it is recognized that knowledge of the laws of health does not unfit a man to be president of the health board, even as a knowledge of law does not disqualify a man for the bench, nor familiarity with finance for the presidency of the Chamber of Commerce. I am sure that I express the sentiment of this association in felicitating the city on the one hand and Dr. Darlington on the other."

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, FEB. 6, 1904.

Deaths reported, 3,852; under five years of age, 998; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 823, acute lung diseases 844, consumption 404, scarlet fever 48, whooping cough 10, cerebrospinal meningitis 12, smallpox 17, erysipelas 22, puerperal fever 13, measles 30, typhoid fever 42, diarrheal diseases 100, diphtheria and croup 108.

From whooping cough, New York 3, Philadelphia 4, Pittsburg 2, Boston 1. From smallpox, Philadelphia 16, Pittsburg 1. From cerebrospinal meningitis, New York 6, Baltimore 1, Boston 1, Fall River 1, Lynn 1, Brockton 1, Gardner 1. From erysipelas, New York 7, Chicago 3, Philadelphia 5, Baltimore 2, Providence 1, Boston 2, Springfield 1, Pittsfield 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,425, for the week ending Jan. 23, the death-rate was 18.1. Deaths reported, 5,304; acute diseases of the respiratory organs (London) 208, whooping cough 121, diphtheria 64, measles 114, smallpox 1, scarlet fever 36.

The death-rate ranged from 2.3 in Kings Norton, to 39.4 in Merthyr Tydfil; London 17.4, West Ham 22.6, Brighton 17.3, Southampton 14.8, Plymouth 17.8, Bristol 19.3, Birmingham 18.4, Leicester 12.6, Nottingham 21.4, Liverpool 22.8, Bolton 21.7, Manchester 20.6, Salford 20.7, Bradford 17.0, Leeds 20.3, Hull 17.3, Cardiff 18.3, Rhondda 20.5, Barrow-in-Furnace 8.7, Wigan 23.2.

METEOROLOGICAL RECORD.

For the week ending Feb. 6, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

DELAYED PUBLICATION.—The continued strike among printers and pressmen is responsible for delays in issuing the JOURNAL.

RECENT DEATHS.

H. LYLE SMITH, M.D., of Hudson, N.Y., died on Feb. 11, in his sixtieth year.

AUGUST KREHBIEL, M.D., a retired physician of New York, died on Feb. 11, in his sixty-fifth year. He was graduated from the University of Würzburg in 1864.

CHARLES AUGUSTUS WHEELER, M.D., M.M.S.S., of Leominster, died Feb. 11, 1904, aged sixty-seven years.

EXAMINATIONS FOR ARMY MEDICAL SERVICE.

THE examination of applicants for appointment as Assistant Surgeon in the United States Army will be resumed in Washington immediately after the close of the present session of the Army Medical School; it will embrace the full examination (as heretofore), at the conclusion of which those found qualified will be commissioned. Full information as to the requisite qualifications for appearance for examination, method of application, nature and scope of examination, etc., may be obtained upon application to the Surgeon-General U. S. Army, Washington, D.C. The examining board will probably reassemble about the middle of April next, and those desiring to present themselves before the board should make application at once. Applicants are restricted in age to thirty years, and one year's hospital experience or its equivalent in private practice is required.

BOOKS AND PAMPHLETS RECEIVED.

Transactions of the American Dermatological Association at its Twenty-seventh Annual Meeting held in Washington, D. C., May 12, 13 and 14, 1903, in connection with the Sixth Triennial Session of the Congress of American Physicians and Surgeons.

Leprosy in the Hawaiian Islands. By Judson Daland, M.D. Reprint.

The Complete Medical Pocket-Formulary and Physician's Vade-mecum. By J. C. Wilson, A.M., M.D. Third Revised Edition. Philadelphia: J. B. Lippincott Co.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, Neurology, Pediatrics, Obstetrics, Gynecology, Orthopedics, Pathology, Dermatology, Ophthalmology, Otology, Rhinology, Laryngology, Hygiene and Other Topics of Interest to Students and Practitioners. By leading members of the Medical Profession throughout the World. Edited by A. O. J. Kelly, A.M., M.D., with the collaboration of twelve others. With regular correspondents in Montreal, London, Paris, Berlin, Vienna, Leipsic, Brussels, and Carlsbad. Vol. IV. Thirteenth Series, 1904. Philadelphia: J. B. Lippincott Co.

Rabies. Its Place amongst Germ-Diseases, and its Origin in the Animal Kingdom. By David Sime, M.D. Cambridge: The University Press. 1903.

THE GENERAL MANAGEMENT OF DIABETES.[1]

BY FREDERICK C. SHATTUCK, M.D., BOSTON,
Jackson Professor Clinical Medicine, Harvard Medical School.

ALTHOUGH pathological knowledge affords the best basis of therapy it is not always the sole basis. We cured malaria long before we knew its cause. Syphilis was controlled long before bacteriology was born, and all that we know of the cause of syphilis to-day is that it must be dependent upon some form of living organism having the power of indefinite reproduction.

When we use the term diabetes mellitus let us clearly grasp the fact that we speak probably of a symptom rather than a disease; that the presence of sugar in the urine means a greater or less impairment, temporary or permanent, of the power of the organism to consume sugar; that while our knowledge of the starting point of such impairment is very imperfect, we have good reason for believing it may be as widely separated as Langerhans' islands in the pancreas, the liver, or several portions of the central nervous system; that during life, at least, we can rarely determine the point of origin in a given case.

Useful as the term glycosuria may be for clinical purposes as denoting the milder grades of the condition, in these brief remarks I shall, for simplicity's sake, include all grades of the failure to burn sugar under the term diabetes. Although we treat a condition and a patient, not a disease and a patient, treatment may be of much value, resulting in prolongation of life and promotion of comfort, sometimes in absolute cure. The means to the end are diet and mode of life, the *rôle* of drugs being, as I am sure my friend Dr. Thomson will agree, a subordinate one.

Prevention, being the highest form of medicine, comes justly first. What can we do to prevent diabetes? Very little. Human life in civilized regions unavoidably tends to become more complex, the struggle for existence fiercer, competition of all kinds, but especially among brain workers, more keen; and we must recognize nerve overstrain as one of the predisposing causes of diabetes. Even if it were practicable and wise to make periodical tests of the sugar-burning capacity of all our adult patients in active life, how many would heed the danger signal of sugar in the urine after the ingestion of a hundred grams of sugar fasting? Some even of the godly say, "Tush! there shall no harm happen unto me," showing an attitude of mind possibly more conducive to happiness and comfort in life than that of Martha, "careful in many things."

I have in mind a man approaching middle age whose great-grandmother, grandmother and mother all died of diabetes, and whose own urine has been saccharine. With such an inheritance it is fairly in place to examine the sugar combustion power of such members of the family as we can, and to enjoin a careful life as to diet and strain. Until we know far more than at present, I do not see much more we can do in either special or general prophylaxis.

Time does not permit, even if the occasion demanded, much detail; and I propose, therefore, to deal mainly with the principles which, as it seems to me, should guide us in the management of our diabetic patients. A diabetic who consults us and has not been treated should, I think, be told to collect his twenty-four hour urine for, say, three successive days, without change in either diet or mode of life, the amount of urine and sugar being important factors in the estimation of the gravity of the case. If, on the other hand, the patient is under rational treatment which has reduced or done away with his sugar it is rarely desirable to let down the bars, as experience shows that sugar production is in many cases more easily controlled the first than on subsequent attempts. In general, with the exception of cases which are evidently very mild or severe in type it seems to me wiser to enforce an absolute or nearly absolute diet at once, — just as it is more humane to complete the shortening of a dog's tail at one rather than in successive operations. The very mild case probably does not require great restrictions. If acetone and diacetic acid are present a radical and rapid change in diet is dangerous. The striking improvement in strength, weight, and general symptoms which we so often see rewards the patient for his self-denial, and thus encourages him to persevere.

So wide is the variation between the different cases of diabetes, and so emphatically do we treat the patient, the more we individualize our patients, applying general principles to special cases, the better results shall we have. The diet list should be adapted to each case. I do not like the printed lists disinterestedly furnished us by some of the manufacturers of food products. They encourage laziness and routine — those two cardinal vices. Moreover, quantity is only next in importance to quality in the food of a diabetic. An approximate adjustment of the amount of food to the requirements of the special case must be aimed at. The body weight should be noted at stated intervals, weekly during the earlier part of treatment, at longer intervals later and in the more favorable cases. I doubt the wisdom or necessity in most cases of such accuracy as some of the modern German writers seem to enjoin; and yet, although it may not be essential for the patient to provide himself with scales and weigh out his portions, nor to dine in scales like Dr. Sanctorius of old, he should be given a rough idea of the size of a given weight of bread, meat, and fat. An increase in the amount of fatty food may be of importance nearly comparable to that of a diminution of starch.

The weight of the patient, his general symp-

[1] Read before the Medical Society of the State of New York at its Annual Meeting, Albany, Jan. 26, 1904. Symposium on Diabetes.

toms or their lack, and the condition of the urine, taken together, will generally prove safe guides as to the judiciousness of the diet. Under a strict diet the sugar and polyuria, one or both, are practically sure to diminish, and may disappear. In a favorable case I expect to see the sugar disappear in two or three weeks, the weight increasing. How long a strict diet is to be maintained must depend upon the type of the disease, which, again, largely depends upon the age and nutrition of the patient. In milder cases I believe it to be wiser to keep the patient on a strict diet for one to two months, and then to test the tolerance for starch, giving first 2 or 3 oz. of bread daily and increasing the amount weekly as toleration warrants. In more severe cases which are rendered sugar free with difficulty one must be more careful in allowing bread, and watch its effect even more closely. In the severest cases, in which the diet does not cause the sugar to disappear, it is ordinarily better to allow a fixed amount of bread. It is certainly so if under the strict diet weight and strength fall off. The sugar is then made from the nitrogenous food or the body tissues and the danger of acid intoxication is increased.

A diabetic who loses weight does so for one of three reasons: His diet is not strict enough; or it is too strict; or, finally, the case is a hopeless one. Every case is a law unto itself. Severe diabetes is not a disease for a lazy doctor to treat, or for a careless or willful patient to well endure.

As I have grown older I find that I have more and more discarded the use of diabetic breads. No diabetic bread which is palatable for any length of time is safe. We must always reckon with human greed for gold, and I much prefer to give ordinary or perhaps graham bread, the percentage of sugar-forming material in which is known, than to run the chance of deluding myself and my patients. I once visited incognito the agency of a well-known company which purveys for diabetics. "Have you bread for diabetics?" "Yes." "How much starch does it contain?" "None." "What! No starch?" "None!" My friend, Professor Wood, however, said the bread contained 60% of sugar-forming material. Gluten flour from another manufacturer had a low sugar-forming percentage one year and a high one the next.

If alcohol is considered desirable it is best given in the form of whiskey or brandy, a brut champagne, Moselle wine, or one of the California hocks, some of which contain practically no sugar.

I have never used the skimmed-milk cure as advocated by Donkin. To remove the fat and leave the sugar does not seem consistent with common sense. I concede that it has worked well in some cases, but wonder if the explanation does not lie in the fact that these patients had been eating far too much and would have done equally well under a diet judiciously restricted in quantity as well as quality.

A day of starvation once every two or three months is very useful in some cases. Austin Flint's plan of keeping a patient in bed from Saturday night until Monday morning, fasting, has seemed to me a good one. If hunger is felt a little beef tea may be a comfort without really invalidating the fast.

The bowels should always receive careful attention. All the more so if acetone and diacetic acid reactions are present in the urine. The skin also should not be neglected. Hot or vapor baths at home followed by active friction, a Turkish or Russian bath at a well-managed establishment, if the general state of the patient permits, are useful adjuvants, especially if the skin be harsh, dry, and inactive. Ralfe thinks he has succeeded in preventing impending coma by the hot bath. In milder cases, with the skin still relatively active, the tonic effect of a daily cool or cold bath, provided that reaction be prompt, thorough, and maintained, is of service. Diabetics are sensitive to cold, and wool or silk underclothing of light or moderate weight is usually desirable. I think we generally err in this country in the colder season by wearing too heavy underclothing. We keep our houses at summer temperature, and voluntarily load ourselves with clothing which we would think justified revolution if a czar compelled its adoption. A diabetic should have several overcoats of varying thickness and warmth, and can scarcely be too well wrapped up while driving in an open carriage, the only form of conveyance really fit to drive in except in stormy weather.

Worry and anxiety are to be avoided as far as possible. Such avoidance is — alas! — only too often easier to enjoin than to secure; but we must do our best. The man of large affairs and responsibility must be helped to systematize his work, to throw every possible detail on subordinates, and to shorten his working hours. How many of us inspect the down-town offices of our patients in active business in order to remedy defects of light, ventilation, and heating of the apartments where more time is passed than anywhere save in the bedroom? In many cases the sum of small advantages forms a large aggregate, and sunshine and open fires are better classed among the greater than the small advantages. In a word, we are dealing with a class of people whose resistance and vitality are more or less diminished; in many of whom, we have reason to believe, the nervous system is especially at fault. The desirability of moderating nerve strain is therefore obvious.

Muscular exercise is useful directly, in that it burns sugar; indirectly, in that it aids blood and lymph circulation. It is therefore peculiarly adapted to diabetics, provided that thought and intelligence govern its use. In excess it is potent for harm. Outdoor exercise is far better than in any confined space, if the condition and circumstances of the patient permit. As to the form — walking, golf, tennis, horseback — it must depend upon the purse

and taste. We are all so constituted that what we enjoy is, on the chances, better tolerated than what we dislike. Calisthenics and the various forms and degrees of massage, carefully adapted to the individual patient, are for the severer cases. Patients debilitated from any cause rightly ask direction as to the amount of exercise they can take. If the intelligent co-operation of the patient can be secured, better results will follow, even in sanitarium treatment; and most diabetics are not, and cannot be, under constant supervision. The best rule I have been able to formulate is the following: The patient is told, "You exercise; you feel tired; you rest an hour and fatigue passes. That fatigue was physiological, healthy, beneficial. If, on the other hand, after you rest you are still tired, you have done too much."

A change of climate during our Northern winter, with all that such change carries with it in freedom from care and in the ability to be in the open air, may be of great importance.

I am painfully conscious of the sketchiness of these remarks, but try to derive some consolation from the thought that, after all is said, is not he the best practitioner of medicine who, reasonable diagnostic acumen being assumed, at the expense of his own gray matter most skillfully adapts general principles to the particular needs and circumstances of the special case? In passing it occurs to me to add that, unless my experience has been exceptional, it is unusual to observe a case of diabetes from start to finish. The very rapid cases are not very common. Others co-operate heartily for a time; the restrictions then become irksome, and they sometimes shun the doctor, partly because they see that he does not attach much importance to drugs, the giving of which still represents too largely in the public mind the function of the physician, and partly because they do not want to exercise the self-denial which they feel will be demanded of them. In the milder cases past middle life perhaps no great harm results. It is the cases of medium severity which are most apt to suffer from this ostrich-like procedure. We can roughly classify our diabetic patients into those of (*a*) severe, (*b*) moderately severe, and (*c*) mild type.

The classification of any given case can usually be more accurately made after than before a suitable diet is enforced, as some cases prove more or less manageable than we expect when we first see them. And yet, classify as we will, there is every possible gradation between the extremes.

I trust that a few illustrative cases will not trespass too much upon your patience. A patient under twenty is sure to be of the severest type, and is, with very rare exceptions, beyond hope; and yet life may be prolonged even for ten years, as in a young man of exceptional resolution and force of character whom I saw several times. A rigid diet should be enforced as long as it can be tolerated and strength and weight are maintained.

I. Two years ago I saw a girl of ten. Polyuria and sugar had recently and inexplicably appeared. Under strict diet she became sugar free for a considerable time. She now, under the same diet, passes about 50 oz. of urine containing 8% of sugar, looks and feels well, and has held her weight.

II. A school girl of eighteen spent Christmas vacation at home and appeared to her mother as well as usual. She returned to boarding school and soon complained of extreme hunger and thirst, with increasing lassitude. Polyuria was also noted. She lost flesh rapidly, and was sent home Jan. 27. She passed four quarts of urine in the twenty-four hours following her return, and the amount of sugar was 4.6%. There were marked acetone and diacetic acid reactions. In spite of large doses of bicarbonate of soda, and without much change in diet, she went into coma, and died Jan. 30, three days after her return from school. The whole process, as nearly as could be ascertained, was of a little less than a month's duration.

III. A man now thirty-eight, active, florid, muscular, weighing 206, consulted me seven years ago for marked polyuria and 4% of sugar. The polyuria was recent, but the sugar was probably of older date, as he had had eczema of the penis the previous summer. Under strict diet in two weeks the urine became normal. There was a slight loss of weight. He now weighs 175 to 180. He is in good general condition, in spite of extreme and unavoidable business worries and hard work the past four or five years. He has relaxed, and again restricted his diet, sugar reappearing in the urine with less provocation than formerly. I doubt if he will attain old age, though I hope I may be mistaken.

IV. A woman of forty-one, weighing 185, entered the hospital in July, 1891, for sciatica. She had a moderate polyuria with about 1% of sugar, varying from day to day. Under treatment the sugar disappeared from the urine, and she was discharged much relieved after a month in the hospital. A brief record in 1897 states that she was looking well, sugar present. Two other records the same year show sugar in her urine in amounts varying from 1% to 1½%. She entered the hospital again in December, 1903, saying she had taken no special care of herself, except to avoid sweet stuffs. During her two weeks' stay in the hospital this time the urine varied between 42 and 72 oz., the largest amount of sugar being 6%, the lowest, under strict diet, $\frac{1}{10}$ of 1%. She was discharged at her own request, the urine still containing sugar; no acetone or diacetic acid reaction at any time. Weight 175. In twelve years she seems to have lost no ground, and her case is probably to be classed as a favorable one.

V. Seven years ago a man, then sixty-three, of large business responsibilities, first consulted me. Ten months before that a competent observer had found no sugar in his urine. I found a moderate polyuria, and a percentage of sugar.

Weight 184. He was easily rendered sugar free, and after a time could tolerate a moderate amount of starch. From time to time he broke loose, has gradually developed a marked arteriosclerosis, which last spring led, through rank imprudence, to a uremic attack. This has necessitated some change in his diet, and he has never fully regained the weight he lost last spring, now weighing 165, and passing about 2% of sugar without polyuria. He feels well and is in active work, having few mental resources outside of his business.

VI. Shortly after this his brother, one and a half years younger, came to me with great polyuria and much sugar, recent in onset. All symptoms disappeared rapidly under diet, and I have not seen him professionally for six years. About that time he was elected to Congress, and has been since active in political and campaign work, feeling very well with moderate dietary restriction. These brothers are fair examples of diabetes coming on after middle life, in well-nourished though not obese persons — the milder type of the disease. It is usually not necessary to enforce an absolute diet in such cases long; moderate restriction can then be allowed. Some of these cases can later return to practically an ordinary diet without reappearance of sugar. The experience of all of you can, doubtless, duplicate such cases as I have sketched.

In the young, treatment can at best only delay the fatal result. In those in the prime of life great service can generally be rendered, though actual cure occurs only in the minority of cases. In those past middle life the disease is usually well tolerated, and may be of comparatively little moment, provided that reasonable care be exercised; and yet, now and then we encounter cases the course of which proves other than first impressions would lead us to expect.

MEDICAL TREATMENT OF DIABETES.[1]

BY W. H. THOMSON, M.D., LL.D., NEW YORK.

THE pathology of diabetes mellitus has been the most elusive subject of modern medicine. Repeatedly during the past forty years we have seemed to be on the verge of important discoveries relating to it, only to find that our uncertainties, instead of being dispelled, had simply taken new forms, which in turn have raised other problems to solve.

It is, of course, due to the great obscurity resting upon the physiological mechanism for the disposal of the carbohydrates of food in the system that the pathology of diabetes has remained so uncertain. Fifteen years ago in a symposium like this, held at a medical gathering in New York City, I suggested that we were yet without any knowledge of a seemingly important factor in the problem, and that was the relation of the muscular tissues to the utilization of the saccharine elements of food. The facts which we did know then were that the muscular tissues were virtually the chief generators of animal heat, and that quite apart from their function of contraction and of relaxation was their function of oxidation, so that the blood collected from the veins of a large muscle like the gluteus, though the muscle were at perfect rest, yet contained less oxygen and more carbon dioxide than the blood of the right ventricle itself, as this latter was mixed with blood from the great glandular viscera, where oxidation is less active than in muscle. This shows how much burning up of blood contents occurs when the blood is coursing through muscular tissue, and as the chief material for such oxidation consists of carbohydrates, some failure in this muscular function might have much to do with the pathological failure of sugar oxidation in diabetes.

This suggestion was received with incredulity, and most of the speakers confined their attention to the supposed relations of the nervous system and of the glycogenic functions of the liver to this disease. Not long afterwards the pancreas in its relation to diabetes came to the front, and has maintained its place as one important factor in the problem ever since. Lately the news comes that O. Cohnheim finds that an enzyme is produced in muscle which if alone does not act upon sugar, but when mixed with the secretion of the pancreatic cells of Langerhans is a very energetic solvent, in the same way that trypsin becomes effective only when conjoined with the kinesic ferment in the intestine.

Until physiology becomes settled, pathology cannot be settled; and, therefore, therapeutics, while matters so stand, must remain mainly empirical. And so I confess that I regard the subject of medical treatment of diabetes, which has been assigned to me, as one to which I can contribute little beyond the results of my experience, based upon written notes of the histories of patients whom I have treated in the course of years.

To the question, When does glycosuria mean diabetes? my answer is that we do not know. That glycosuria, limiting that term to dextrosuria, is an epiphenomenon, appearing in the most diverse connections, we all know. Like albuminuria, it occurs too often and too variously as a temporary accompaniment of different disorders to be rated as frequently no more than a symptom. In the case, however, of albuminuria we usually can form some conception of its causation. But with glycosuria we do not know whence it cometh nor whither it goeth; and, therefore, we can never be sure what its significance is. Hence, I feel skeptical about the assurance with which some pronounce offhand a given case as one only of glycosuria and another as surely diabetes, because in my experience some patients come with both a moderate and an intermittent presence of sugar in the urine, and with no consti-

[1] Read before the Medical Society of the State of New York at its Annual Meeting, Albany, Jan. 26, 1904. Symposium on Diabetes.

tutional disturbance, but who in time develop into confirmed diaoetics, while others may come with very saccharine urine and severe constitutional symptoms, only to improve under treatment and finally get well. Nor does the recent date of the disorder make much difference. Some begin suddenly and soon develop grave symptoms, and then become permanently free from their trouble, while others begin just as suddenly and never get well. The only valid distinction which I admit is that the presence in the urine of diacetic acid, shown by the ferric chloride test, is generally indicative of confirmed diabetes.

My practice, therefore, is to pronouce a glycosuria which has lasted more than a year diabetes. Time, in other words, and not the variability either of the glycosuria or of any other accompaniments, is my ground for diagnosis. Persistent glycosuria in its way is much the same as persistent albuminuria in its way, that is, each means that the patient has a serious disorder; and *pro tanto*, it does not much matter what name we choose to tack to the disorder when the question is how we are to treat it.

As it is the patient, and not his named disease, which is to be dealt with, all factors entering into his story have to be taken into account; and the first of these facts is age. The rule is, the younger the patient, the worse it is for him. Why it should be so I do not know. The chief significance of this fact, however, is that it points to diabetes as a deeply seated constitutional disorder, and not a localized disease of any one organ, pancreas or other. In keeping with this inference is the hereditary or family proclivity to the disease in instances too numerous to be accidental, and equally so the greater liability of certain races to it. In my experience there is no race which is so subject to diabetes as the Jews. The bearing of this clinical fact upon what remedies we are to expect the most from, and also what reputed remedies we are not to expect much from, we will soon note.

The next consideration to age is the state of the nutrition of the patient. I always make it a point to determine what the daily output of urea is, as well as the amount of sugar passed. If the percentage of urea is continuously high there is real emaciation going on, even if the patient be fat. The sugar itself, indeed, may disappear, but the urea excretion may remain one-half more or double what it ought to be. The patient must have medicines for that.

The patient may be obese. This condition calls for special medication on account of danger from the heart. If he has oxalates alternate with abundant uric acid crystals in his urine, all the oetter for him. He may be a profitable patient to us for years, though, *pace* glycosurists, he should not be allowed to forget that he has diabetes, and so on. All I wish to illustrate by this preface to my subject, announced on the card as "Medical Treatment of Diabetes," is that I would prefer to have it read, "Medical Treatment of Diabetic Patients."

As to medicines, I would begin with the statement that I but rarely prescribe opium, codeine or any other of the opium derivatives; and I beg leave to take a short time to explain why, in such a constitutional disease as diabetes, I cannot regard this drug as of real service, though it has been long and generally recommended in textbooks. Nervines, such as opium, belladonna, strychnin. aconite, etc., are agents which affect certain functions of the nervous system. They, therefore, are only functional remedies, and they have no power whatever in therapeutic doses to directly affect structure or nutrition, however long they be prescribed. All that they ever do is temporarily to produce some functional symptoms, but they never affect the texture or the nutrition of tissues or organs, either beneficially or injuriously. Therefore, none of them can touch diabetes itself any more than they can touch typhoid fever; however, some of them may relieve for a time some serious symptoms in both diabetes and in typhoid fever. As a veteran teacher of materia medica, I used to urge that no functional or symptom medicine, such as the nervines, could be expected to modify an organic disease in any way, either for good or evil, the only exception being in the case of colchicum,[1] which can produce organic changes. Alcohol produces organic changes only by virtue of its chemical and not by its nervine properties. One of the most powerful nervines for properties is nicotine. There is a great deal of functionally active nicotine in a cigar. Let any one who has never smoked a cigar try it, and he will soon illustrate what nicotine can do. Now, my father, my grandfather and my great-grandfather began to take nicotine by smoking tobacco about the same time of life that I did, namely, at twelve years of age, and continued the same to the last year of their lives, which was at the age of eighty-eight, eighty-seven and ninety-two, respectively, while I am well on to my three-score and ten. Can nicotine, therefore, not injure the bodily mechanism? Never, in rational doses, for like all other nervines, in such doses it can neither do permanent good nor permanent harm.

To this class of functional medicines belongs opium and its derivatives; and, therefore, diabetes continues progressive, however continuously or fully opium is prescribed. A functional medicine is one whose whole action can be secured by one dose. Its hundredth dose does not do any more than the first dose does, sometimes not as much, for with many of this class,

[1] Dr. Norwood of Alabama, well known for Norwood's Tincture of Veratrum Viride, narrated to me how five young men in his neighborhood, while on a "spree," broke into a country doctor's office, in the doctor's absence, and drank to his health out of a bottle of wine of colchicum, which they mistook for sherry. Two of them died, but Dr. Norwood saw the survivors a number of weeks afterwards, when they had lost all their hair, including their eyebrows, and were as generally yellow as persons recovering from cobra snake venom. Now, recovery of healthy persons from the most dangerous degrees of poisoning by opium, belladonna, aconite, etc., is generally complete after twenty-four hours, with no lasting nutritional change whatever.

as with tobacco, the system becomes used to them. A man may for many years relieve an asthmatic attack by stramonium, but it is not his disease — asthma — which is thereby dealt with, but its symptom, bronchial spasm, and his last dose of stramonium does not do more for him than the first dose did, taken years before. More efficacious against his asthma itself would be arsenic and potassium iodide, which no more act in one dose than mercury does in syphilis, or iron in anemia. The fundamental difference between functional medicines, which influence only functions, and organic medicines, which change the nutrition of tissues or organs, would be more widely recognized but for the confusion which exists in many minds about the term "function." Because function is deranged whenever organism is deranged, therefore it is supposed that the converse of this statement is equally true, namely, that a derangement of function must always imply a corresponding derangement of organism. A simple illustration will show the difference. The function of an oil lamp is to give light. Derange the mechanism of the lamp by a leak in the globe, or by an injury to the wick-holder, or by the loss of the wick, and the light-giving function of the lamp is correspondingly deranged. But the entire mechanism of the lamp may be perfectly intact, and yet it will give no light because the source of its function, namely, the oil, is changed by mixing it with water. So a steam engine may be perfect in every detail of its mechanism and yet not go because the source of its function, namely, the coal, is lacking. So in the living mechanism, its functions need power therefor, and that power is in the blood. Functional medicines act only on and through the blood, and not on the tissues. This being so, functional medicines can act only temporarily; they have to be renewed just as the oil in the lamp has to be renewed, though the lamp itself remains the same indefinitely. The oil can remedy no injury to the mechanism of the lamp; and likewise every functional medicine is powerless against a truly organic injurious change going on in the living mechanism.

Functional medicines we need constantly in practice to relieve symptoms, or to meet emergencies. They are indispensable for such purposes, but we should always remember that they are powerless against an organic injurious change going on in the living mechanism. All which a functional medicine can do is to deal with a temporary derangement, not in the structure but in the working, that is, in the function, of the body; and this it does immediately in one dose. But no specifically permanent changes should be expected from it. Opium may affect the symptom, sugar in the urine, by temporarily diminishing it, but it has no effect on the disease causing that symptom.

We must look elsewhere in such a constitutional disease as diabetes than to such functional medicines as opium, and I notice that of late experience is leading many physicians to abandon its use in this disease. For a number of years I have advocated the free use of cod liver oil in diabetes. I was specially led to do this by its remarkable effect in the case of two brothers whom I treated thirty-two years ago. The first, an active business man, aged thirty-five, came to me with polyuria, thirst, emaciation and progressive loss of strength, for which he had been treated unavailingly for a year with the usual course of diet and drugs. He then took larger doses of cod liver oil than any patient in my experience, for he said that he never measured it, but took it directly from the bottle as a drink, followed by Vichy water. In another year's time he was cured, and he has remained well ever since. His brother, two years younger, came to me the following year with much the same condition, as far as the great quantity of sugar in the urine was concerned, but he suffered in addition from general bronchitis. He found that he could stomach cod liver oil as well as his brother, and with equally good results. The younger the patient, the more persistently I urge the taking of this remedy, and I adopt every resource to make its free use possible by the patient, by the administration with it of pepsin and bismuth. So long as the stomach does not rebel, diabetic patients of this class cannot take too much cod liver oil. Whether this oil acts as a substitute for the starchy elements, or whether it spares the proteids from disintegration, or whether it acts as a nerve food, or whether it acts by increasing the red corpuscles, I do not know; but as an empirical fact I can testify that it both diminishes the sugar and the excess of urea eliminated whenever it is taken freely and is well borne. As in all cases where we aim at influencing nutrition by any measure, it must be used both systematically and perseveringly. Obesity contraindicates it, and likewise I should not give it to patients of very sedentary habits; but it is quite useful with many elderly people.

Next to cod liver oil, I would mention iron. As before remarked, I have long suspected diabetes as largely a muscle disease, and throughout the animal kingdom muscular power is directly proportioned to the intake of oxygen. As iron can act in us only in its capacity of an oxygen carrier, I try to give diabetics all the iron which they can take, along with all the fresh air which they can get. As iron in many forms tends to cause constipation, which itself not infrequently becomes a serious trouble to diabetics, a very serviceable preparation for them is the old-fashioned Hooper's Pills, whose formula is: ℞. Ferri sulph. ℥ss; powdered senna, powdered jalap, cream of tartar, powdered ginger, each gr. xii. Ext. gentiani q. s. M. Div. in pil. * * *

The progress of medicine in our time has added a class of remedies which are coming more and more into daily use, and to which I would apply the term medicinal, in distinction from surgical, antiseptics. They include a

varied list of phenol derivatives, among which I would include quinine, for sooner or later we may look for its synthetic production from coal tar, as well as the salicylicates and the benzoates. In this class of medicinal antiseptics I would also include arsenic.

It is not improbable that one of the properties of this class of medicines is to start the activity of various enzymes, which in particular states cause derangement of metabolic processes in the body, or lead to disintegration of its tissues. We are only beginning to get some insight into the relations which certain internal secretions bear, on the one hand, to the assimilation of food or, on the other, to the neutralization of poisons in the system, or to the disintegration of the tissues themselves. One of the most striking facts in this connection is the singularly small quantity of the secretions themselves which seems to suffice to maintain the important functions which they subserve. Thus the total extirpation of the pancreas in dogs induces a fatal diabetes. This diabetes is ascribed to the removal of the scattered glandular structures in the pancreas, called the islands of Langerhans. But if three-fourths of the pancreas be excised, so that only one-fourth remains, the small remnant of these island cells is yet enough by their secretion to prevent glycosuria. This indicates that this internal secretion is of the nature of an enzyme, which can propagate its action from very small beginnings. The small bodies, called the parathyroids, have recently been proved to be essential to life, owing to their internal secretion neutralizing a virulent poison, generated most probably in the alimentary canal, and which poison causes fatal tetanic convulsions. So excision of three-fourths of the kidneys, leaving only one-fourth of kidney substance, is followed by death, preceded by great polyuria, with such excessive excretion of urea that it seems as if the proteid tissues were undergoing rapid dissolution. This remarkable result is ascribed to the kidneys, having as their function not only to excrete, but also to regulate, the production of urea by an internal renal secretion.

However that may be, I have for some time been much interested with cases which have come under my observation of excessive secretion of urea which, in a way, resembles saccharine diabetes. On the 5th of last month I was consulted by a healthy looking young man, aged twenty-three. He seemed to be a typical neurasthenic, for his complaints were that two years ago he had a sudden nervous breakdown, ever since which he could not apply his mind to anything. He has a constant sense of fatigue, is very nervous and dyspeptic, especially intolerant of starchy food and very insomnic. His pulse was soft and weak. Examination of his urine showed that he passed no less than 51 gm. of urea a day, while according to his size and on his restricted diet, he should normally pass only 22 gm. The total solids of the urine amounted to the high figure of 114.37 gm., or 1,715 gr. There was no albumen, nor casts, nor sugar in the urine by any test, and he had no fever. His family history was decidedly unfavorable in the respect of neuroses, one brother being in an asylum, an elder sister with something like cyclical insanity, and another sister, younger than himself, is abnormally fleshy.

I put him on the same treatment that I would a diabetic, namely, a shellac-covered capsule, containing 5 gr. of sulpho-carbolate of soda and 1 gr. of potassium permanganate, to be taken half an hour after meals and at night; and one hour after meals t. i. d. a powder of 10 gr. of sodium sulphate and 10 gr. of sodium benzoate. On the 16th he came again, remarkably improved in all his symptoms. His urea had fallen from 51 gm. to 30 gm., and the total solids had decreased 250 gr. To add now 10 gr. of aspirin to each dose of the sulpho-carbolate, or 40 gr. per diem. On Jan. 16 he reported that he was able to do more work than he had done for some years, and that he was now studying to pass a university examination.

I believe that if physicians, instead of being content in their examinations with discovering whether there were abnormal ingredients in the urine of patients, would also uniformly investigate whether the normal ingredients were present in their healthy proportion, more cases of this kind would be found than are generally suspected. What special process led to such abnormal waste in this patient I do not know, any more than what the real processes are which underlie the disease diabetes. The processes of the chemistry of life are altogether too complex, and too imperfectly understood as yet for us to make more than doubtful guesses. But as an empirical fact, I am sure that I succeed better in controlling diabetes mellitus, as far as the use of drugs goes, by a persistent and free administration of antiseptics than by any other means, cod liver oil and iron excepted. In such a disease the therapeutic tests should be sought for only in severe and prolonged cases; and I will beg leave, in illustration, to cite briefly one such history. He was a gentleman, aged forty-two, who after a year of severe mental strain noticed that he was passing water very often, and that his shirt when wet by the urine was stiffened by it. He was put on diet, opium and codeine, by his physician; but as he was steadily losing flesh and strength and was subject to alarming attacks of syncope, he finally consulted me. I first saw him after one of these attacks. He was cyanosed and extremely dyspnoic. Another attack soon occurred, in which he seemed to be passing into diabetic coma. For sixteen years after this I conducted the management of his case, watching him very closely, as he was a most intimate friend of mine, and though I never found sugar absent from his urine, during those sixteen years he ably performed the exacting duties of chief editor of one the largest of New York's daily newspapers. He then moved to another city, to enter upon a much less exacting business. I

warned him that he was by no means a well man, and that he should continue his treatment without change. I learned, however, that he became quite careless, and in three months he succumbed to an attack of bronchitis. Such histories of years of active life while keeping up treatment, soon followed by fatal decline on cessation of the same, have occurred more than once in my experience. Nature does not cure diabetes.

As remarked before, I would include arsenic in this class of antiseptics, as it comes nearer in its properties as a medicine to such agents than to any other. My usual practice is to combine it in the same prescription with them, and, therefore, I ordinarily give arsenious acid itself, watching for the development of arsenical symptoms, just as in prescribing it for any other purpose. Some of the liquid preparations, as Fowler's solution, the Lig. arsenici hydrochlorici or the bromide of arsenic, have the advantage that the dose may be increased or diminished more readily; but I have failed to note any special advantage in changing the form of the drug, because it is arsenic itself in them all to which the effect is due. As to the rest, their administration should be varied from time to time, on the general principle that the too continued use of any drug tends to lessen its efficacy, or in the case of the salicylicates to irritation of the kidneys. If called to a patient who is voiding so large an amount of sugar that a speedy reduction of it is imperative, I would give 15 gr. of antipyrin, with the same of sod. benzoas, four times a day. After a time I would substitute 15 gr. of aspirin with 10 of bismuth salicylate. In subacute cases, illustrative prescriptions would be somewhat as follows: Benzosal gr. 48; Sodium benzoate dr. 4; Arsenious acid gr. 1; Sodium salicylate dr. 11. Make 48 capsules. Two an hour after meals and at night. Or, Sodium sulphocarbolate dr. 2; Salicin dr. 1; Phenacetin dr. 2; Ammonia benzoate dr. 4. Make 48 capsules, shellac covered. Two a half hour after meals; and if there be much insomnia, 20 gr. of strontium bromide and 15 of antipyrin at night. Of course, each physician can vary such medication according to indications. A weekly dose of blue pill is nearly always beneficial to patients after middle life. Unless the patient be much emaciated, one of the means which works well to prevent the tendency to constipation is a powder, dissolved in a tumbler of hot water and sipped slowly on rising, of a drachm and a half of sod. bicarb., half a drachm of sod. sulphas. and of magnes. sulphas. each, and 10 gr. of sod. salicylicas.

Alkalies, in the form of mineral waters, have always held a deserved place in the treatment of diabetes. There is, however, one caution to be always borne in mind, and that is that the free use of all saline water tends to increase the waste of the system, so to speak, and they should not be given to any one who is really losing flesh. I think that I have seen them do harm to emaciating diabetics.

Diabetes is a very serious disease on one account alone, if not on other accounts, in that it virtually compels a starvation of an essential element of food. The system must have sugar, and if it does not get the sugar which it can use in the food, it will turn to its own proteid for sugar. Along with this profound perversion poisons begin to be generated, of which oxybutyric acid and its derivatives are doubtless only a part, and which poisoning we are practically unable to neutralize. Our function, therefore, is to put off the evil day of these terminal developments as long as possible; and to do that, I am sure that merely functional medicines will afford us no help. The essentials of the chemistry of this specific toxemia are yet unknown. The formation of acetone and of diacetic acid occurs early, but the blood itself often changes its color, owing to the abundant presence in it of fatty and of proteid granules. Something, however, holds back the carbon dioxide in the tissues, for it is a mistake to ascribe the low percentage of carbonic acid in the blood to its hyperacidity, because the blood of these patients when drawn will take up oxygen or carbonic acid about as freely as normal blood. The last step is the rapid disappearance of sugar from the urine. Why sugar is absent in diabetic coma we do not know, but significantly enough the first danger signal comes from the kidneys, for before drowsiness begins the urine often deposits an enormous number of peculiar looking casts. To postpone the well-nigh inevitable death in these conditions, I rely upon the most trustworthy diuretic which we possess, namely, prolonged intestinal irrigation with hot normal saline solution, by means of the best instrument for the purpose which I know of, Kemp's rectal irrigator. Hypodermic injections of 7 to 14 gr. of camphor in sterilized almond or olive oil answer best to sustain the failing heart, while diluted milk holding all the sodium bicarbonate which the patient can take is the only recourse left for food. Some of the fatal poison doubtless could be washed out if we could bleed the patient freely and transfuse an equivalent amount of normal saline.

A COMPARISON BETWEEN THE MEDICAL USES OF THE X-RAYS AND THE RAYS FROM THE SALTS OF RADIUM.[1]

BY FRANCIS H. WILLIAMS, M.D., BOSTON.

THE greater interest in the salts of radium lies in their relation to science, especially to physics and chemistry; but as they can be of service in medicine, it will be instructive, I think, to attempt to estimate the probable value in this field of the rays which they emit; we will not consider the emanation. Perhaps this can best be done by comparison with another

[1] Read at the Annual Meeting of the Boston Society for Medical Improvement, Jan. 18, 1904.

Lantern projections were shown of a frog taken by the Beta and Gamma rays together, by the Gamma rays alone and by the x-rays; projections were also shown of a number of patients, chiefly with superficial cancers, who had been successfully treated by the x-rays. The fluorescence excited in willemite by pure radium bromide was also shown.

form of radiation, namely the x-rays, which has been in use for nearly eight years and has had time to give proof of its value in diagnosis and treatment.

The beautiful radiographs that can be taken by the x-rays make them of great assistance in surgical diagnosis in cases of fractures and diseases of the bones, for example, in the location of foreign bodies and in the detection of most varieties of calculi, whether in the kidneys, ureters or bladder.

Radiographs and the fluorescent screen render valuable assistance in medical diagnosis. An aneurism of the aorta in the early stage can be detected more certainly by an x-ray examination than by any other method, and its progress can be watched in a way that has hitherto been out of the question. Mediastinal growths, the size and position of the heart and central pneumonias, for example, can be recognized better by means of an x-ray examination than by any other method. The question as to whether or not fluid is present in the chest is sometimes doubtful by the usual physical examination, but its absence can be determined by means of the fluoroscope. The great service of which the x-rays are capable in the most fatal of all diseases, pulmonary tuberculosis, deserves especial emphasis and cannot be repeated too often; the diagnosis of this disease in an incipient stage can be made with more certainty by the aid of the x-rays than is otherwise possible; it may sometimes be satisfactorily made before there are any definite physical signs in the chest. The frequency with which this disease occurs and the opportunity which an early diagnosis offers for successful treatment make the x-rays peculiarly valuable when there is a question of this disease; moreover, not only is the proportion of recoveries larger in the early stages, but also the patient is obliged to give up much less time to the restoration of his health than is necessary when the disease is further advanced, a very important consideration.

The abdominal cavity offers less opportunity for the use of the x-rays, but this is a field which can be further cultivated.

The x-rays are also useful as a therapeutic agent. They may not only relieve the pain that accompanies cancer, but also pain produced by other causes, that of intercostal neuralgia, for example; they may be employed as what, for want of a better name, I may term a tonic and a cardiac stimulant; they may be used for the treatment of skin diseases and new growths; many cases of skin diseases and many forms of superficial new growths, especially face cancers, have been healed by their means.

I attempted some months ago to make a comparison between the results following the use of surgical treatment of new growths and those I had obtained in 150 cases of new growths that I had treated by the x-rays, up to Jan. 1, 1903, but was unable to find tables giving exactly the percentage of success to be expected in different forms with the usual surgical treatment. Such statistics would be helpful in estimating the value of the x-rays and of radium.

The outline given above is sufficient to indicate the directions in which the x-rays are of assistance; now let us consider what can be expected from radium salts as an aid in diagnosis, whether by means of radiographs or by fluoroscopic examinations or as a therapeutic agent. To this end it is necessary to appreciate the fact that this new substance, which belongs to the class Mme. Curie has called radioactive, emits three kinds of rays, named by Rutherford Alpha, Beta and Gamma, which differ greatly in their power of penetration, the Alpha being the most easily absorbed and the Gamma the most penetrating.

Radium salts are unlikely to be of any service in diagnosis by means of radiographs, for if the Beta and Gamma rays are used together (the Alpha do not need consideration, as they are so easily absorbed), the radiograph shows no differentiation between the tissues; if the Gamma rays alone are used, there is a slight indication of the bones, but the results cannot be compared for a moment with those made by the x-rays. Further, the time required is very long, many thousand times that needed for taking a photograph by the x-rays, unless the radium is placed close to the photographic plate, that is, within the fraction of an inch.

Let us next consider whether radium will be of any service in fluoroscopic examinations. The two sides of the chest can be compared in cases of pneumonia or pleurisy, for example, by placing the fluorescent screen on the front of the patient's chest and the radium salts, due precaution being exercised, on the back. The practitioner may thus be able to determine whether or not one part of the chest is denser than the other by watching the fluorescent screen, as it will be less brightly illuminated, of course, on the side where the increased density occurs. For thus observing the chest the Gamma rays only should be used, for if the Beta and Gamma rays were employed together there would be risk of burning the patient; moreover, the Beta rays would be of no advantage, because they would be largely absorbed in the body, as their power of penetration does not compare with that of the Gamma rays. This method of examination would be a very crude one, as these rays have little power to differentiate the tissues.

It is, then, only in the comparatively narrow field of therapeutics that we may expect radium salts to be of value. Dr. William Rollins of Boston was, so far as I am aware, the first to appreciate that this new substance would probably be of service in the treatment of certain diseases. At least two or three years ago he put into my hands a metal box with an aluminum front, containing some chloride of radium, and at his suggestion I employed it for therapeutic purposes, but the radium to be had at that time was too weak to give definite results.

The strength or, to use the term generally

employed, the radioactivity of a given specimen of radium salts is estimated by comparison with that of uranium as a unit. The weaker qualities of radium, which it is comparatively easy to obtain, have a radioactivity of 1,000 or 8,000 or considerably more, but the pure radium salts, which can be had with difficulty only, have a radioactivity of about 1,500,000.

Recently I have employed the pure radium bromide in 50 cases, as described below, using generally 50 mgm. when making an exposure, but on some occasions amounts varying from 10 to 100 mgm. I have abandoned the use of the weaker salts, as they are inefficient.

The 50 cases are divided as follows:

One case of acne, 2 of psoriasis, 5 of lupus vulgaris, 2 of lupus erythematosus, 2 of eczema, 1 of keloid, 5 of rodent ulcer, 28 of epidermoid carcinoma and 4 breast cases.

The case of acne healed under the use of the radium, each pustule being exposed through an opening in a thin sheet of lead foil. The two cases of psoriasis were treated in certain areas with radium and in others by means of the x-rays, for purposes of comparison; healing took place much more quickly in the parts which were exposed to the radium than in those exposed to the x-rays. The two cases of lupus erythematosus are still under treatment. Two of the five cases of lupus vulgaris have healed, and three are under treatment and doing well; in one of these cases a comparison was made between the action of the radium and that of the x-rays, the upper half of a large patch, which involved the greater part of the side of the face, being chosen for the application of the radium, as the disease seemed most severe in this area. The area thus treated has largely healed, whereas less progress has been made in the tract exposed to the x-rays. The same is true of the one case of keloid; the half treated by radium has nearly disappeared, but that treated by the x-rays has only somewhat improved.

The two cases of eczema, on the contrary, did not improve rapidly under the use of the radium, and the itching was not relieved; therefore this treatment was stopped and the x-rays applied.

Three of the five cases of rodent ulcer have healed, and one has nearly healed; the fifth deserves special mention. In this case the growth is very extensive, has involved the side of the face and oroit and has penetrated deeply; it has been operated on several times during the past twenty years, and when a recurrence took place after the last operation was treated by the x-rays, and yielded to this treatment. Later an extensive recurrence took place, which the x-rays on further trial *did* not and which the radium *may* not heal, but the radium has checked the growth of the rodent ulcer and has arrested the rapid loss of strength of the patient. This case would indicate that radium is more efficient than the x-rays.

Fourteen of the 28 cases of epidermoid carcinoma have healed, thirteen are still under treatment and one has discontinued treatment and been operated on for the third time. This patient had a growth on the tongue which was operated on twice. A second recurrence then took place; the x-rays and radium were applied, but although some improvement followed their use, it was not sufficient to warrant the delay of a third operation. In another of the cases of epidermoid carcinoma, in which the new growth was widely distributed over the cheek and a considerable portion of the upper lip, both the radium and the x-rays were used. The part treated by the radium healed more promptly than that exposed to the x-rays.

Three of the four breast cases were recurrences after operation; the radium diminished the indurations in the scar or in the parts in its neighborhood. These indurations yielded more readily to the radium than to the x-rays. The fourth case was a patient who was suffering from carcinoma and who had refused operation. In this case the diseased area was treated both by radium and the x-rays. The results are not yet definite.

In some cases the rays from radium act as an analgesic.

It is evidently the Beta rays which play the greater part in the healing process, rather than the Gamma rays, although the Gamma rays may contribute; but as the exposure in my cases has been, as a rule, from one to three minutes in duration, there would hardly be time for the small proportion of Gamma rays to exert much action. Experience has shown that irritation may be caused in some patients after one minute's exposure to the Beta and Gamma rays together, whereas I have found that an exposure of forty-five minutes to the Gamma rays alone produces no irritation.

The patient and the practitioner must be protected from radium, as they must be from the x-rays, or burns may result a week or two after the undue or, in the case of the practitioner, the unnecessary exposure. Patients vary in their susceptibility to the effect of radium salts, and therefore the dose must be varied to suit the individual patient. The burns caused by radium, like those produced by the x-rays, are, it is said, very difficult to heal. I have had no experience with them.

I am now studying the question as to whether or not radium salts can be of service in treating deep-seated new growths. We have seen that the Beta and Gamma rays together cause healing in cases in which the disease is near the surface, but as the Beta rays are readily absorbed, they will not be of value for the deep-seated growths. I tested the penetrating power of the Beta rays by separating them from the Gamma and then placing my little finger in their path, and found that by this obstruction the Beta rays were largely absorbed. I am now using the Gamma rays in certain superficial cases, by covering the radium capsule with an aluminum cap that shuts off the Beta rays altogether, but does not obstruct the passage of

the Gamma rays. If the Gamma rays cannot cause healing in diseases near the surface, their use as an agent for treating deep-seated new growths may be abandoned. On the contrary, if the superficial cases yield to the Gamma rays, it will be well to study their effect on deep-seated growths. Under no circumstances should the Beta and Gamma rays be used together for deep-seated diseases, because the Beta rays would cause serious injury before the Gamma rays had time to produce a beneficial effect.

Radium as a therapeutic agent has certain advantages when compared with the x-rays. Obviously a grain or two of radium salts is far more convenient as a source of radiation than a large, cumbersome apparatus. The radium is always ready for use, and the amount of radiation it gives off is uniform, so that, without having recourse to the fluorometer to measure the output, as in the case of an x-ray tube, the dose can be adjusted exactly in two ways, — either by varying the time during which the part to be treated is exposed or by varying the distance of the radium from the patient. Radium can also be better used in cavities.

The healing action of radium salts, as ordinarily used, that is, when the Beta and Gamma rays are employed together, is limited to parts on or near the surface of the body or its cavities, and to a small area, unless the radium capsule is moved from place to place. The x-rays, on the contrary, can act at one time on the whole side of the trunk. On the other hand, certain superficial new growths yield to radium that do not to the x-rays, and the action of the radium is more prompt. Whether or not these results will be permanent time only can show.

Since many superficial new growths are healed by radium or the x-rays, although more slowly by the latter, it is quite possible that in many cases it would be an advantage to use both forms of radiation, either on the same or on alternate days.

Summary. — (1) The rays from radium salts, unlike the x-rays, are not serviceable in diagnosis either by means of radiographs or of fluoroscopic examinations.

(2) The Beta rays are useful as a therapeutic agent in certain skin diseases and new growths, if the diseased tissues are superficial or are not more than about 1.25 cm. (one-half an inch) below the surface of the skin or accessible mucous membranes.

(3) The Beta rays from radium salts will heal some cases of new growths that are not healed by the x-rays, and they act more promptly, but not over so large a surface at one time as the x-rays.

(4) Radium salts of an activity of 8,000, or considerably more, are not sufficiently strong to be efficient. Pure radium salts, which have a radioactivity of about 1,500,000, are not too strong for the work to be done.

(5) The radiation from radium salts, unlike that from the x-ray tube, is uniform.

(6) Great care should be exercised to avoid burns.

THE PROGNOSIS OF IDIOPATHIC PLEURISY.[1]

BY GEORGE G. SEARS, M.D., BOSTON,

Visiting Physician, Boston City Hospital; Assistant Professor of Clinical Medicine, Harvard Medical School.

THE statistics which form the basis of this paper are drawn from 439 cases of pleurisy which were treated in the Boston City Hospital between the years 1880 and 1895. They include those only in which no suspicion arose that the acute attack was a secondary manifestation of some process already existing. The possibility of a previous tuberculosis, as shown by a history of cough for several weeks, of hemoptysis, hip disease, etc., was thought sufficient to exclude, and none are included which appeared in the course of pneumonia, typhoid fever or other acute disease. They are grouped together as instances of acute, idiopathic pleurisy, the pleurisy *a frigore* of the older writers, without regard to their possible etiology. They have been studied with the sole purpose of determining whether they threw any light on the question of prognosis, which, apart from its immediate interest to the individual, has assumed economic importance since life underwriters have begun to consider that an attack of pleurisy is sufficient to postpone the acceptance of a risk until a certain period of probation has elapsed. No attempt has been made to trace their later history except in the mortality records in the state archives, which, owing to the shifting character of the population from which they are drawn, can at best contain only a portion of the actual deaths which have occurred among them. Eighty-six (20%) of these 439 cases are known to have died within seventeen years, and this number should possibly be increased by 23 who are classed in the following table as "doubtful" because the hospital record and the death certificate failed to tally sufficiently closely to make identification absolutely complete. If the latter are added the percentage of the dead rises to 25. Their length of life after the attack of pleurisy is given below, the doubtful cases being included in brackets.

Number died within 2 years	30	(5)
Number died 2 to 5 years later	26	(6)
Number died 5 to 10 years later	15	(9)
Number died 10 to 15 years later	13	(2)
Number died 15 to 17 years later	2	(1)
	86	23

The cause of death appears in the following table:

Cause of Death.	Identified.	Doubtful.
Phthisis	45	13
Pleurisy	5	1
Empyema	1	0
Bronchitis	3	0

[1] Read at the Annual Meeting of the Boston Society for Medical Improvement, Jan. 18, 1904.

Cause of Death.	Identified.	Doubtful.
Edema Lungs	1	0
Pneumonia	6	4
Meningitis	3	2
Intestinal Obstruction	1	0
Nephritis	3	0
Apoplexy	2	1
Heart	5	2
Typhoid	2	0
Chronic Hepatitis	1	0
Gastritis	1	0
Alcohol	2	0
Accidental	5	0

The difficulty of connecting the deaths with the attack of pleurisy is obvious in many of these cases. A fatal result from accident, alcohol, apoplexy, heart disease, gastritis or chronic hepatitis shows no reasonable dependence on it; on the other hand, suspicion arises when the cause is assigned as nephritis (amyloid kidney?), pneumonia or typhoid that the whole truth may not have been told, and that an effort has been made either to avoid the necessity of notification or to save the small insurance which many of them carry, and which might have been forfeited if a frank declaration of tuberculosis had been made. Mays' recent analysis of the death returns from pneumonia and phthisis gives distinct emphasis to this point, since he shows that the number of deaths from the former is relatively much greater in the states where notification of tuberculosis is compulsory.

The relation is clear where death was attributed either to pleurisy or empyema, of which there were six instances. It is more than probable, considering our present ideas as to the etiology of cases of idiopathic origin, when some form of tuberculosis has been assigned, of which there were 45 cases, and probable where death has been certified as occurring from edema of the lungs of five months' duration, bronchitis or meningitis (seven cases). The case of intestinal obstruction may also belong to this class, but without this there are 58 (13%) where the connection seems very probable, or, including the doubtful cases, 74 (17%). Their length of life after the attack of pleurisy is given in the following table, the doubtful cases appearing in brackets:

Under 2 years	23	(4)
2 to 5 years	18	(6)
5 to 10 years	7	(4)
10 to 15 years	9	(2)
15 to 16 years	1	
	58	16

The table shows that over 39% of the deaths among the patients who could be definitely identified had occurred within two years, and over 70% within five. This ratio is not materially altered if the doubtful cases are included. The number whose death occurred within two years is noteworthy; some of them might have been omitted as victims already of a well-marked tuberculosis if a more detailed history had been given or if an autopsy had been held.

A similar series of cases, drawn from the records of the Massachusetts General Hospital, was more fully reported by Dr. R. C. Cabot, in that he was able to trace a considerable portion that were still living. It was his conclusions, which were much more optimistic as to the ultimate outcome than those usually accepted, which stimulated me to make the present investigation. He found among 300 patients that 117 (39%) were known to be living and well from two to more than twenty years after their discharge, more than half of whom had been followed for over ten years, while 31 (10%) had died. Of the latter group 17, more than half, had died of some form of tuberculosis, and 6 others were then suffering from a tubercular process. 43.5% had contracted tuberculosis within five years, and 78% within ten. 146 patients could not be traced. A comparison of these figures with those furnished by the City Hospital shows that in the former 7.6% of all cases are known to have developed tuberculosis against 13% in the latter; while of the total deaths 55% of the former and 67.4% of the latter were attributable to some condition presumably connected with the original attack of pleurisy. Cabot brings out the striking fact that among the Massachusetts General Hospital cases 67% of those who became tuberculous had tuberculosis in their immediate family or in their own past history, while only 25% of those who had remained in perfect health for five years or more were so tainted. This difference was not noticeable among the City Hospital cases, possibly because the earlier records were often silent regarding the family history. In both series the percentage of cases with recurrent attacks was about 3% (3% and 3.8% respectively).

The sources of error in the interpretation of these figures are many and obvious. They do not appear, however, to justify so hopeful a view as Cabot has expressed, but rather to give reason for the suspicion that an attack of pleurisy may be a manifestation of a constitutional taint, which may be the cause of death years after apparent recovery. How great the danger is they do not show, for the only conclusions which they justify are these:

(1) That about 10% of these cases are known to have developed tuberculosis.

(2) That over 55% of all cases which were followed to their death had died from some form of tuberculosis.

(3) That tuberculosis, when it occurred, developed within five years in over 50% and within ten years in over 70%.

(4) That this danger is much increased by a tubercular family history or a personal history of some form of tuberculosis previous to the attack.

Clinical Department.

MASSACHUSETTS GENERAL HOSPITAL.

CLINICAL MEETING OF THE STAFF HELD AT THE TREADWELL LIBRARY, DEC. 12, 1903.

(Concluded from No. 7, p. 186.)

A CASE OF RUPTURED SPLEEN. OPERATION AND RECOVERY.

BY G. W. W. BREWSTER, M.D., BOSTON.

JENNIE W., aged six, was brought to the accident room of the Massachusetts General Hospital July 2, 1903, with a history of having been run over by a team. Examination by the house physician showed slight pain in the right leg and a little abdominal tenderness around the umbilicus, with bruises over the legs and back. No one saw the accident, and no facts as to the severity of the injury were obtained. She was sent home and told to report to the Out-Patient Department the next day. Examination the next day by Dr. Greenough in the Out-Patient Department led to the child's being sent into the hospital for observation. He was suspicious of some abdominal lesion.

On entrance again to the hospital the examination showed a temperature of 100.2, pulse of 132 and respiration 44. The abdomen was generally distended, with muscular spasm and slight tenderness in the region of the umbilicus. The child was seen by Dr. S. J. Mixter, who advised an immediate operation. The parents would not consent and decided to take the child home against advice.

The same night I was called in consultation by the family physician. I found her with a temperature of 102, pulse 130. The abdomen distended but not tender, somewhat rigid, and dull in the flanks. She was drowsy and though she had been restless, was now stupid. The mother said she had vomited three times during the afternoon. It was explained to the family that the child ought to be operated upon, and that it was her only chance. At that time it seemed probable that there was a ruptured intestine. Finally she was taken back to the hospital and prepared for operation.

As there was nothing to indicate in what part of the abdomen the lesion, if present, existed, I made a median incision just above the umbilicus. On opening the peritoneum dark-colored free blood escaped. This welled up from the pelvis, and fearing a lesion in that part of the abdomen, I rapidly enlarged the opening down to the pubes. After sponging the pelvis free of blood with large pieces of gauze, no lesion could be found. On exploring the left side a small amount of blood was seen trickling down from the region of the splenic flexure. In the mesentery of the descending colon was a small hematoma. The incision was enlarged by cutting across the left rectus. On walling back the intestines with gauze a fissure was seen near the lower pole of the spleen, from which venous blood was trickling. There was no large hemorrhage, but only a small flow of blood. This was entirely controlled by the pressure of two strips of gauze, the ends of which were carried out of an opening in the flank. The abdominal opening was then closed. The cut surfaces of the rectus were sutured with buried chromic catgut and the rest of the incision closed with "through-and-through" silkworm gut sutures.

The wound healed by first intention and the patient was discharged at the end of four weeks.

REPORT OF A CASE OF BONE CYST OF A DIGITAL PHALANX.

BY E. A. CODMAN, M. D., BOSTON.

I want to show this case on account of the rarity of the disease and because the operation and its result are interesting.

This patient is about forty. She came to the Out-Patient Department of the Massachusetts General Hospital in the spring of 1900, complaining of a swelling of that portion of the middle finger, on the left hand, represented by the middle phalanx. There was an enlargement on the sides and dorsum of the finger. It was painless and of bony hardness and not in the least tender. The patient had noticed the swelling of the finger for many months. There was no history of injury or any disease of the bone in other portions of the body. She was otherwise in good health and always had been. There was no specific history.

The surgeon who saw her at the time, suspecting syphilitic dactylitis, prescribed iodide of potassium. She took this faithfully for a while, but it did no good. The phalanx continued to enlarge, and in the spring of 1901 she returned again to the hospital under my care. The accompanying skiagraph shows the tumor at intervals of a year, and the appearance is characteristic of medullary sarcoma. I felt that amputation was indicated, but, bearing in mind the good results which were obtained without amputation from simple excision of medullary sarcoma, I decided to remove the middle phalanx alone and allow the digital phalanx to drop back on the proximal. Under cocaine I removed the affected phalanx with its periosteum, leaving the tendons intact. The wound united by first intention, and for some days, owing to the filling of the space from which the phalanx was removed by blood clot, the finger presented almost a natural appearance. As weeks and months passed, however, a shrinking of the tissues took place and the terminal phalanx was slowly drawn towards the proximal. As the tissues between the phalanges became firmer, the flexor and extensor tendons began to control the movements of the distal phalanx, so that now you will see that there is a very marked flexion and pretty decided extension. She can hold a 5 lb. weight on the flexed finger tip, and the finger is quite useful. The presence of the fingernail makes the cosmetic result much more agreeable to the patient than the stump of the amputated finger would have been. On sawing open the phalanx after it was removed it was found to be a shell of bone containing a cavity filled with straw-colored serous fluid and lined by a soft translucent myxomatous membrane. The cavity was crossed here and there by fine trabeculæ.

Dr. Whitney, from the gross appearance, considered it a myxo-chondroma, but unfortunately the decalcified sections were lost and I have no microscopic report. It seems probable that the tumor was at first an enchondroma which later had undergone a myxomatous degeneration. Bone cysts are very rare in any portion of the body, and as far as I can find this case in a digital phalanx is unique. It is not unlikely that such cysts are formed by the degeneration of chondromata, though it has also been supposed that a blood clot caused by trauma may have sometimes been the original lesion.

The result of the operation is at least interesting, though had I known beforehand what the

tumor was, I should simply have packed the cavity or perhaps done sub-periosteal excision of the phalanx.

Medical Progress.

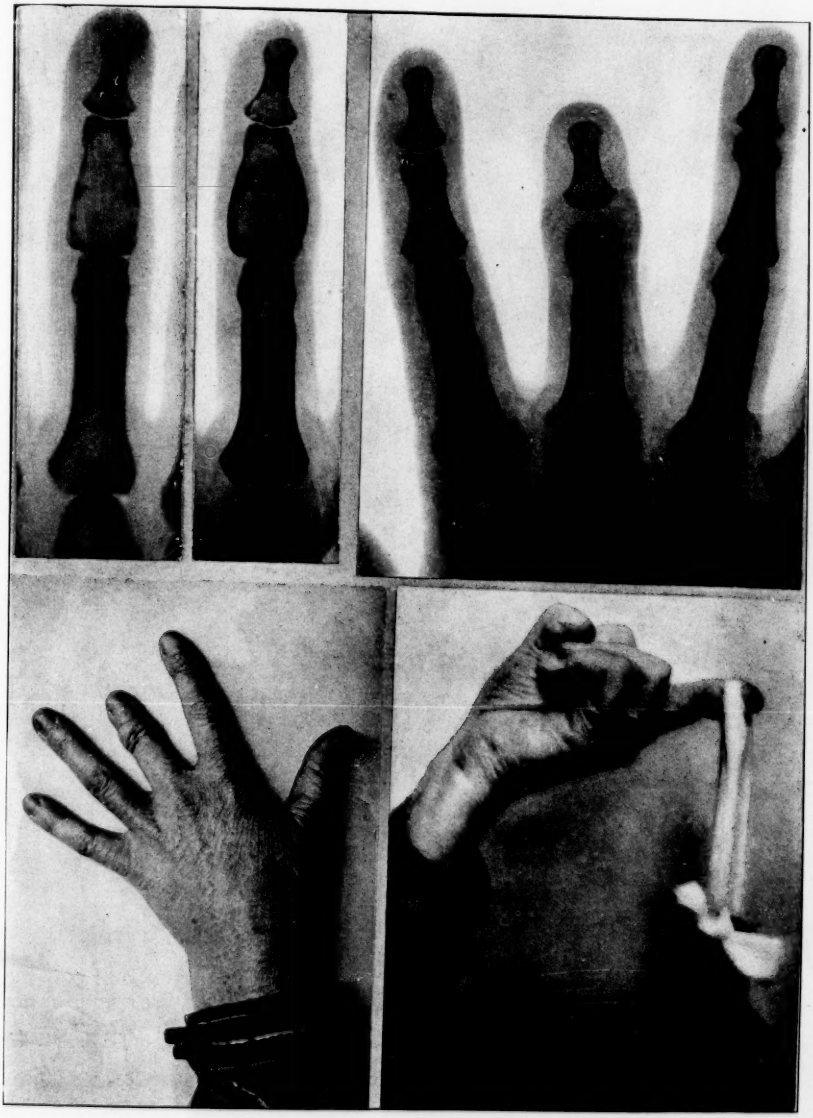
RECENT PROGRESS IN LARYNGOLOGY.

BY A. COOLIDGE, JR., M.D., BOSTON.

(Concluded from No. 7, p. 189.)

THE REGENERATION OF THE NASAL MUCOUS MEMBRANE.

THE regeneration of different tissues has been recently extensively studied, especially in Italy. The mucous membrane of the nasal cavities is a complicated structure, and one which in recent years has suffered much at the hands of enthusiastic operators. The processes of repair of this membrane have been carefully studied by Citelli,[7] using the material of Gradenigo's clinic in Turin. A small piece of mucous membrane was removed from the turbinate in many cases, and after the end of from two to sixty days a larger piece, including the previous wound, was removed and examined. Two days after the removal of the first section, the wound surface and the epithelium bordering it was covered with a fibrinous exudate containing leucocytes and red blood corpuscles, which remained until the eighth day. The epithelium in the neighborhood of the wound contained leucocytes and showed signs of necrosis. Most of the glands which were injured by the operation and the erectile tissue, to a greater or less distance from the wound, showed a similar necrosis. The process of repair began in the first few days by proliferation of the oval and round cells of the deeper layers of the epithelium. In eight or ten days these formed the greater part of the epithelium of the new cicatricial tissue. This epithelium was also in part supplied by the glands which escaped destruction in the wounded area. The glands which lay under this area, by vigorous proliferation of the epithelium of their ducts, established an outlet through the newly forming tissue and contributed to the formation of the superficial epithelium. There did not appear to be any reproduction of glands nor any formation of ducts by the invagination of surface epithelium. The erectile tissue showed but little attempt at regeneration, but the necrosis seldom included much more than what was injured by the operation. The granulation tissue which appeared within a few days after the operation arose chiefly from the capillaries and small veins of the superficial layers of the epithelium, and only to a small extent from the underlying erectile and connective tissue. These experiments tend to show that in the removal of superficial parts of the nasal mucous membrane the glands and the erectile tissue are commonly not destroyed. The superficial layers of the mucous membrane are replaced by connective tissue, by the shrinking of which a depression is formed which may be of considerable therapeutic value in cases of obstructed respiration. The removal of the whole turbinate, which was formerly a common operation, is now properly abandoned, since the normal function of the nose is endangered. With the galvano-cautery it is difficult to control the extent of the destructive process, and the time of healing is prolonged.



[7] Archiv. f. Laryngol. und Rhin., Bd. xiv, Hft. 2.

THE ARCH OF THE PALATE.

When some years ago it was suggested that the high narrow palate with crowded teeth was the result of adenoid vegetations and proved their past or present existence, this statement was commonly accepted without question. Later this dictum was questioned, and even by good authorities denied. The subject has been recently studied and discussed, with a growing conviction that the causes of the high palate are many and often obscure. Two able papers on the subject appeared a short time ago, one by Swain [8] and one by Bentzen.[9] Swain argues well in opposition to Grosheintz [10] that the upper jaw cannot fail to be affected by abnormal conditions during the years of its development, of which conditions nasal obstruction and mouth breathing are the more common and important, but that other influences may change the shape of the palate is shown by a comparison of the skulls of flat-head Indians with those of other tribes. The paper should be read as a whole to do it justice. In discussing the cause of the arch of the palate the author points out that in the newborn babe the hard palate at the height of the arch is considerably above the level of the Eustachian tube. In the child at puberty it is considerably below the Eustachian tube. Consequently the palate has grown away from the base of the skull by the downward growth of the superior maxillary bone, the septum and the pterygoid processes, so that the palate may be said to grow down instead of up. It would be easy to believe that in an obstructed nose this growth would be retarded, as any growth is retarded by faulty function. Also the child who goes around with his mouth open tends to have the muscular force, the weight of the jaw, the lack of the restraining influence of the upper lip and the streaming of the air through the mouth which adds to the buccal tension and removes

[8] Trans. Amer. Laryngol. Asso., 1903.

Bone Cyst of Phalanx.

the tongue away from exercising any influence upon the upper jaw, all tending to draw down the outer side of the superior maxillary bone. Another factor in the shape of the adult palate, as well as the alignment of the second teeth, is the preservation of the deciduous or milk teeth and in general the care of the teeth of the young child. The circumference of the horizontal arch and the perfect anterior curve are influenced by the retention of the first teeth as long as possible. Of all the arguments presented by dentists, the strongest evidence is that which appears when we consider the trifling force they are constantly using to spread the abnormally contracted jaw in order to give space for replacing the teeth that are out of line. The author concludes that it is possible by deforming processes which artificially alter the shape of the skull to produce a change in form and shape of the hard palate; that in considering the various causes which produce the abnormalities of the palate, we must lay stress upon the lack of proper aëration of the maxillary sinuses retarding their development and hence that of the whole superior maxilla. The conservation and general care of the deciduous teeth help to produce a normal horizontal curve in the hard palate and lessen the tendency to narrowing.

Bentzen's paper, or more accurately treatise, on the etiology of the high arch reviews the literature of the subject and contains the records of many measurements. The literature shows that most authors consider mouth breathing as the cause of the high arch. The opposite theory of Siebenman and his followers looks upon it as hereditary or developmental. The author's researches show that there is no definite relation between the height and breadth of the hard palate, but there may be greatly differing ratios within normal limits. The height of the palate increases up to the twenty-fifth year, after which it recedes, whereas the breadth increases through life. The most rapid growth in breadth is just after the second dentition; in length after puberty. Men have a broader and women have a narrower and relatively higher arch. As a rule, individuals with adenoid vegetations have a higher arch than those without. A curious fact appears that in leptoprosopic skulls the arch is low and in chameprosopic skulls high before the second dentition, whereas after that period the opposite is the rule. This applies both to cases with adenoids and those without. The V-shaped as well as the high arch is much more common with mouth breathing than without; they are more common in males than in females, and in leptoprosopia than in chameprosopia. In conclusion it may be said that after other influences have determined the height of the palatal arch, this height will be increased by adenoid vegetations.

COCAINE.

The use of cocaine in operations upon the upper air passages is the subject of a paper by Bodine.[11] A thorough knowledge of the limitations of this drug, together with a perfected technique in its use, is to be acquired only by patient, persistent effort. Wide variations in strength of solution and manner of application obtain in different patients and in different parts of the body of the same patient. Not only is the manner of introduction of the solution essential, but the psychic element in the patient is to be considered. Actual vasomotor paralysis occurs in proportion to the patient's nervous susceptibility. The acquirement of a personal calmative in the operator is essential. In surgery of the upper air passages, local anesthesia is especially advantageous — we command the cooperation of the patient; his ability to voluntarily cough and expectorate are to our advantage. A greatly diminished number of fatalities from cocaine poisoning are now encountered in current literature, a decrease due to the weaker solution employed. The urethral mucosa is as effectually anesthetized by application of a 2% solution as by one of 10% strength. In all infiltration work it is important to remember that to anesthetize the skin or mucous membrane the injection is made into the skin, not beneath it. If acid secretion covers the nasal mucosa it is of advantage to use a nasal douche of bicarbonate of soda before applying the cocaine. Cocaine will bear momentary boiling without chemical change, though the practical sterility of the solution may be assumed if freshly prepared with sterile salt solution. Cocaine acts by paralyzing the sensory nerves; acute local anemia and pressure are invaluable accessories in producing this effect. Morphine is a reliable antidote to cocaine poisoning; even in profound morphine narcosis cocaine is the quickest and safest antidote. They antidote each other. Crile has lately shown that the nerves of the pharynx and larynx, especially around the glottis and the terminals of the recurrent laryngeal, are endowed with strong inhibitory functions. Rough manipulation of these regions, such as often occurs in removal of adenoids and foreign bodies, and in laryngotomy, may induce alarming and even fatal collapse through reflex inhibition of heart and respiration. Crile and Matas have found that cocainization of a nerve absolutely prevents reflex impression. In connection with surgery in the region of the larynx, he states that the extensive experimentation justifies his statement that cardiac and respiratory inhibition is impossible if the area be cocainized.

THE INFECTION OF THE CERVICAL GLANDS THROUGH THE TONSILS.

This has been the subject of several papers during the past year. Koplik[12] in reviewing the subject points out that the tonsils have long been studied as a seat of tuberculosis, and the literature is quite voluminous on this theme. Conclusions vary because one set of observers has studied the disease from clinical, while another

[11] Laryngoscope, April, 1903.
[12] Amer. Journ. Med. Science, November.

has analyzed pathological material. Tuberculosis of the tonsil may be a primary isolated process unaccompanied by tubercular foci elsewhere; this is exceedingly rare. Several authors speak of primary tuberculosis of the tonsil with accompanying tuberculosis of the cervical lymph nodes. The disease may be limited to these organs, or may spread thence and involve other organs. Secondary forms of tuberculosis of the tonsils are very common, in which tonsilar infection follows pulmonary tuberculosis. In both the primary and secondary forms the cervical lymph nodes are quite constantly affected. Children furnish by far the greater number of cases both of tonsilar tuberculosis and the form of the disease in which the tonsil draws into the infection the cervical lymph nodes. In some cases the tonsil appears normal, in others hypertrophied, the external surface showing no erosions or ulcerations; in fact such pathological appearances are extremely rare. In all the forms the cervical lymph nodes may be enlarged. The largest nodes and those supposedly first affected are found high up behind the tonsil. The affected nodes form a packet, stretching from behind the angle of the jaw along the greater vessels towards the clavicle. Many cases of tubercular cervical adenitis have been shown to have had tonsilar tuberculosis undoubtedly primary, and there is no reason why the tonsils should not admit tubercular infection as well as pyogenic or diphtheritic infection.

The author concludes that the tonsil is the seat of primary tubercular infection, though rarely as compared with the pyogenic forms of infection. The tuberculous tissue is found in the form of giant cells and tubercular nodules; cheesy degeneration is not common; as a rule the lymph nodes leading from the tonsil are affected. Tonsilar tuberculosis may be the source of a general tuberculosis. As far as the cervical lymph nodes are concerned, when found the seat of isolated tubercular infection of a primary nature, it can be justly claimed that such infection has proceeded from the tonsil.

A general discussion of this subject, in which several papers were read, was held by the Section of Laryngology of the British Medical Association at its last annual meeting.[13]

THE OPERATIVE TREATMENT OF MALIGNANT DISEASE OF THE LARYNX.

In spite of the fact that this subject has been discussed for years and that recent discussion presents nothing essentially new, it is well to repeat principles which seem to be gaining ground, although not universally accepted. These principles may be briefly summarized as follows: An early diagnosis and treatment are of primary importance. Intralaryngeal methods are to be condemned. Under modern surgical proceedings an exploratory thyrotomy, followed if necessary by a generous removal of tissue, is not a very dangerous operation, and in case of a circumscribed growth is comparatively rarely followed by a recurrence. For a good argument on the subject the reader is referred to a paper by Sir Felix Semon read at the last annual meeting of the British Medical Association.[14]

As a general principle operation should be at once proceeded with if the case lends itself at all to operative interference as soon as the diagnosis is made. We must distinguish between intrinsic and extrinsic malignant disease of the larynx, the former comprising the true interior of the larynx from the ventricular bands downwards, the latter the tumors situated on the aryteno-epiglottic folds, the arytenoid cartilages, epiglottis and the posterior wall of the cricoid cartilage. The distinction from a practical point of view is all important. The intrinsic form remains much longer a purely local affection, and shows very little tendency until the disease is much advanced to infect the neighboring lymphatic glands. Upon this fact depends the enormous difference between the two forms with regard to prognosis, extent and danger of the operation.

We possess at present five different operative methods of dealing with malignant disease of the larynx. The intralaryngeal method, with some extremely rare exceptions, is absolutely unsuitable for the radical extirpation of malignant disease of the larynx. After opening the larynx the affection is generally found much more advanced than appeared from laryngoscope inspection. The advantages sink into insignificance in comparison with the dangers which loss of precious time and undue postponement of really radical operation brings about.

In cases of intrinsic malignant disease in which the diagnosis is made when the disease is not too extensive, thyrotomy and thorough removal of the growth with a sufficient circumference of healthy tissue is an ideal operation.

Partial extirpation of the larynx in which no less than one entire wing of the thyroid and possibly an arytenoid and parts of the cricoid cartilage are removed does not offer any greater technical difficulties than mere thyrotomy.

Total extirpation is an operation which cannot be described as a pleasant one, but in extrinsic malignant disease and particularly when it is situated on the posterior surface of the cricoid cartilage, the smaller operations are of no avail.

Sub-hyoid pharyngotomy is suitable for cases in which the disease starts from the epiglottis or from the aryteno-epiglottidean fold, and its technique is an easy one; but a curious fatality has reigned over this operation, the causes of which have not as yet been sufficiently elucidated.

Whilst the microscope may be of infinite value in deciding the question of diagnosis, its *rôle* in this question is that of a helpmate, but not of an infallible arbiter; the clinical observer must have the courage of his own opinions, and in suspicious cases perform an exploratory thyrotomy.

Reports of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

NINETY-EIGHTH ANNUAL MEETING, HELD IN ALBANY, JAN. 26, 27 and 28, 1904.

ALGERNON T. BRISTOW, M.D., of Brooklyn, president.

FIRST DAY, TUESDAY, JAN. 26.

PRESIDENT'S INAUGURAL ADDRESS.

DR. A. T. BRISTOW, in this address, called attention to the fact that the present membership of the state society was 1,135, and of the county societies, 5,680, and estimated the membership, if the two state organizations should combine, at 5,700. He declared that the time was ripe for putting an end to the strife of the past twenty-two years, and expressed the hope that not only would this be done, but that, in the near future, distinctive sectarian titles would no longer be recognized by the state.

REPORT OF COMMITTEE ON CONFERENCE.

DR. HENRY L. ELSNER of Syracuse presented this report, which has already been extensively printed by the medical press. He was followed by DR. A. JACOBI of New York, who urged all to forget the past in the pleasure of this supreme moment, when they were about to end all schisms. He then brought the question of consolidation and unity to a climax by moving the adoption of the following resolutions:

"*Resolved*, That the report of the Joint Committee of Conference be accepted, and that the proposed agreement for the consolidation of the Medical Society of the State of New York and the New York State Medical Association be and the same is hereby approved, and the president of the society is hereby authorized and directed to execute the same in the name and on behalf of the society, and the secretary is hereby authorized and directed to affix the corporate seal thereto; and be it further

"*Resolved*, That the committee of the society, heretofore appointed for the purpose of bringing about the consolidation, be and is hereby continued as such committee, with full power and authority to do whatever may be necessary to carry the agreement into effect."

These resolutions were unanimously adopted.

TIC DOULOUREUX AND OTHER NEURALGIAS FROM INTRANASAL AND EXCESSIVE ACCESSORY SINUS PRESSURES.

DR. SARGENT F. SNOW of Syracuse read this paper, based on an experience with 20 chronic cases. In every one of these there was present either intranasal pressure or an accumulation in some of the sinuses, and in none of the cases was it necessary to resort to excision of the nerve to obtain relief.

ENURESIS.

DR. GEORGE E. BEILBY of the State Industrial School at Rochester presented a paper on this subject. He had had exceptional opportunities for studying this condition, as it was present in from 4 to 10% of the population of that institution. His paper was founded on a study of the records of 75 well-marked cases. In only a few of the cases was there any marked phimosis, and the urine was almost uniformly normal. Of the 75 cases, 60 had nocturnal enuresis, 2 diurnal and 13 both nocturnal and diurnal enuresis. It was very significant that 71 of the 75 patients were confirmed masturbators. The author's conclusion was that the majority of the cases were dependent upon an abnormal irritability of the lumbar enlargement of the spinal cord. His treatment consisted in circumcision, for its mental and moral effect, the use of cold spinal douches, counter-irritation over the lumbar spine and the use of antispasmodics.

TOXEMIA IN TUBERCULOSIS OF THE CERVICAL LYMPHATIC GLANDS.

DR. ARTHUR W. ELTING of Albany reported a case of supposed Hodgkin's disease occurring in a patient twenty-six years old, in which, after the removal of the glandular mass by operation, the patient's condition became very critical, apparently from the entrance into the circulation of a quantity of toxins set free during the operation. Microscopical examination showed the glands to be distinctly tuberculous.

SYMPOSIUM ON DIABETES. PATHOLOGY.

DR. R. M. PEARCE of Albany opened this symposium by a discussion of the pathology. He reviewed the well-known theories and facts bearing on the etiology of this disorder, laying special stress on the recent work inaugurated by Opie. He pointed out that diabetes practically never occurred in the interlobular form of chronic pancreatitis, but in the interacinar form, in which the islands of Langerhans were often involved, diabetes was not infrequent. In 23 cases of cancer of the pancreas collected by the speaker glycosuria was present in only three, and in these cases there was distinct involvement of the islands of Langerhans. It was an interesting fact that when the pancreas was the seat of destructive processes these islands proved more resistant than the surrounding tissues.

PHYSIOLOGICAL CHEMISTRY OF DIABETES.

DR. DAVID EDSALL of Philadelphia, Pa., discussed this subject. He detailed certain experiments on birds and frogs, showing a relation between the liver and pancreas in the matter of the production of glycosuria. He was inclined to believe that there was a greater variety of sugars than was generally believed. In diabetes there might be a defect in glycogen construction, or an excessively rapid conversion of glycogen into sugar.

MEDICAL TREATMENT OF DIABETES.

DR. WILLIAM H. THOMSON of New York presented this paper. He said that he very seldom prescribed opium or its derivatives for diabetics, believing that they not only were incapable of permanent good, but were in themselves deleterious. As a matter of experience he had learned that persons suffering from diabetes who were not very obese often improved very decidedly under the administration of cod liver oil, and that they tolerated large doses of this remedy. Iron and arsenic were also beneficial. In severe cases he began the treatment by prescribing 15 gr. each of antipyrin and benzoate of sodium, four times a day, and, after a time, substituted 15 gr. of aspirin and 10 gr. of bismuth salicylate. Alkaline waters were often of benefit, but it should not be forgotten that all such waters were apt to cause emaciation if given for a long time.

GENERAL MANAGEMENT OF DIABETES.

DR. F. C. SHATTUCK of Boston read this paper. He favored the adoption at once of a rigid diet, but

in the mild cases after one or two months it was proper to cautiously test the patient's powers of tolerating starch. If diacetic acid and acetone were present in the urine, a radical change in the diet was dangerous. The speaker said that he had but little faith in the diabetic breads, personal investigation having shown their unreliability. If such a bread were made so as to be palatable it would not be a safe article of diet to continue for any great length of time. Diabetics should be warmly clad, and should lead a life free from fatigue and anxiety. The amount of exercise to be taken must be carefully graduated to the individual needs.

THE OCCURRENCE OF DIABETIC AND NON-DIABETIC GLYCOSURIA IN THE SAME INDIVIDUAL.

DR. HEINRICH STERN of New York was the author of this paper. It may be summarized as follows: Diabetic glycosuria is nothing more than the salient feature of the second stage of the diabetic deterioration. Glycosuria is a symptom of many other disturbances, both ectogenous and endogenous in origin. Duplex melituria is the result of two concurrent or intercurrent affections of dissimilar character having the one symptom, glycosuria, in common.

CONFLICTING CLAIMS OF GENERAL EDUCATION AND PROFESSIONAL EDUCATION.

ARTHUR T. HADLEY, LL.D., president of Yale University, addressed the society at its evening session, taking the above for his theme. He said that in the professional school there was a greater intensity of application, but this was attained at a sacrifice of some breadth of view. The sooner a man's brain began to turn to his life work the better, but the later a man's horizon became narrowed to the sphere of his special activities, the better also. The true system of education should help men to broaden their mental and moral horizon even while they were concentrating their vision on their specially chosen work. It should not be necessary to shorten the college course, but this should be made to include within it all of the scientific studies that it was practicable to embrace.

PRESIDENT'S ADDRESS, "THE PRESENT STATUS OF THE MEDICAL EXPERT."

DR. A. T. BRISTOW of Brooklyn delivered an address on this subject. He denounced the sneering criticisms of courts on the character of medical experts as libels on a noble profession, and declared that the evils, which all admitted to exist, were not related to the personal character of such experts, but were inherent in the antiquated and very faulty mode of legal procedure. In the first place, it was a most pernicious rule which placed the youngster just out of college and hospital on the same level with men in the profession full of years and rich experience. Another source of confusion was the hypothetical question, a device often so constructed as to prevent the witness from telling more than a part of the truth. If the legal profession showed a greater inclination to assist in this much-needed reform, it would be possible in time to have laws enacted which would secure the calling of properly qualified experts, and would make their testimony less biased than at present.

SECOND DAY, WEDNESDAY, JAN. 27.

THE SUBMERGED TONSIL.

DR. THOMAS J. HARRIS of New York read a paper with this title. He said that the submerged tonsil was usually of the hyperplastic form. The general symptomatology embraced attacks of peritonsilar abscess and of non-suppurative tonsilar inflammation, pain in the throat, the collection of mucus in the throat, with, perhaps, annoying cough or earache. The ordinary operation of tonsilotomy secured only the partial removal of the tonsil. The treatment which he recommended was the thorough separation of all adhesions of the tonsil and then the complete removal of the tonsil by means of the tonsilar punch. His own practice was to operate upon one tonsil at a time, at an interval of a week, doing the operation under cocaine anesthesia.

SOME PHASES OF CHRONIC LARYNGITIS.

DR. Z. L. LEONARD of New York presented this paper. He reported several different types of cases, and emphasized the general amenability of the affection to rest of the part, change of climate and, perhaps, of occupation.

A PLEA FOR ACCURATE KNOWLEDGE IN THE DIAGNOSIS AND TREATMENT OF CHRONIC SUPPURATIVE OTITIS MEDIA.

DR. J. F. MCCAW of Watertown pointed out the necessity for examining every case of chronic suppuration of the middle ear for obstructions in the nose and nasopharynx, and urged that the treatment, to be successful, must be based upon the pathological conditions found to be present.

IRRITABILITY OF THE BLADDER IN WOMEN.

DR. R. L. DICKINSON of Brooklyn read this paper. He classified the chief causes according to their frequency, as follows: (1) Inflammation of the base of the bladder, at times the after-result of gonorrhea; (2) uterine, ovarian and tubal trouble; (3) inflammations about the meatus; (4) urethritis; (5) hyperemias of masturbation; and (6) prolapsed conditions. Cystoscopy of the base of the bladder was easily done with the woman in the knee-chest position, but it was important, in the average woman, to make use of the smallest size of Kelly's instrument, and, after the nature of the trouble had been discovered, to carry on the treatment through a still smaller instrument.

FIFTEEN YEARS' EXPERIENCE WITH UTERINE FIBROIDS.

DR. W. E. FORD of Utica presented in this paper the results of a study of 162 cases, which had been followed long enough to know the ultimate result of treatment. This number included 37 single women. In his earlier years he had treated 96 cases by the galvanic current, using a pressure of 40 volts and from 50 to 150 milliamperes. Of these 96 cases, there were 7 in which both tumors and symptoms disappeared. In 26 there was a symptomatic cure. The accuracy of these statements was attested by the fact that 25 of the cases had been followed for five years or more. He was not at all in sympathy with those who attributed all sorts of dire results to the galvanic treatment, for most of them could be better explained in other ways; moreover, he had met with no accidents except in one case. In that one, the patient died of infection arising from an unrecognized gonorrheal salpingitis. He had tied the uterine arteries per vaginam in a number of cases but had soon abandoned the method as hazardous, difficult and useless. He had lately stopped the bleeding produced by uterine fibroids by the administration of suprarenal extract. He had operated upon 61 women for fibroids, 34 of them by Baer's method.

Probably not more than 20% of the cases of fibroids required operation.

RESULTS IN DIFFUSE SEPTIC PERITONITIS TREATED BY THE ELEVATED HEAD AND TRUNK POSITION.

Dr. Russell S. Fowler of Brooklyn said that before the employment of this position the mortality in this class of cases was 25%. The paper reported an experience with 100 cases, many of them being profoundly septic and almost moribund at the time of the operation. There were 67 recoveries. The general method of treatment consisted in sponging accessible infected areas and flushing successively with a mixture of equal parts of soda solution and peroxide of hydrogen, and with salt solution. Finally, the same procedure was employed in the pelvic and abdominal cavities, using a large Chamberlain tube, and a large tube was inserted in the pelvis and brought out through the abdominal wound, but was dressed separately therefrom. Immediately after operation the head of the bed was raised at least one foot. Of the 33 deaths, 17 occurred in the first twenty-four hours after operation.

ASTHENOPIA; A CLINICAL STUDY.

Dr. D. H. Wiesner of New York said that if the pain were near the eye the asthenopia was probably due to some refractive error, but if further away it was more likely to be of muscular origin.

(To be continued.)

ANNUAL MEETING OF THE BOSTON SOCIETY FOR MEDICAL IMPROVEMENT, JAN. 18, 1904.

A. L. STONE, M.D., SECRETARY.

Dr. E. O. Otis: I desire to express my appreciation of the exceedingly interesting and valuable paper which Dr. Sears has presented to us. A series of statistics, such as these, relative to the end results of pleurisy are of very great value, particularly with regard to the etiology of the disease. Whether or not all cases of primitive pleurisy will eventually be found to be of tubercular origin, as Damanoy and other French authorities seem to think, it is a fact attested by the experience of us all that many cases make a permanent recovery, even when the evidence points to a tuberculous infection. As illustrative of this I recall the case of a family of four children under my care some fifteen or more years ago. Two daughters died of pulmonary tuberculosis, one at the age of about seventeen years and the other somewhat older. A third girl developed acute pleurisy, for which I aspirated her several times. She made a complete recovery and subsequently went through the Boston City Hospital Training School for Nurses, became a nurse and remained well thereafter. The fourth member of the family, a young man in the Massachusetts Institute of Technology, also had acute pleurisy, for which he was aspirated. He likewise recovered and was enabled thereafter to devote himself to the arduous duties of a mechanical engineer and so far as I know is at the present time well and attending to his professional duties. From the family history I have always believed that these two cases of acute pleurisy were of tubercular origin, and yet they made complete and lasting recoveries. If, as we now know, pulmonary tuberculosis is curable in so many cases, why should not tuberculous pleurisy likewise be permanently recovered from? The useful and practical lesson to be learned from such a discussion as this, it seems to me, is that we should bear in mind the possibility of a tubercular origin in every case of apparent primitive acute pleurisy, and exercise great care not only in the treatment of the acute stage but in the convalescence, and see that the patient is placed under such hygienic conditions that he will, as speedily as possible, regain complete expansion of the lung — indeed treat the convalescent from acute pleurisy much as we treat an incipient case of pulmonary tuberculosis by the open-air method.

Dr. George B. Shattuck: Dr. Sears' paper serves once more to emphasize the importance of having in mind the question of tuberculosis in all cases of pleurisy which present themselves to the medical practitioner. The percentage of deaths and recoveries, and the period of intervention between the attack and recovery, or the reverse, undoubtedly would be found to differ in a series of statistics made up on hospital cases and on private patients, or those outside of hospital services, and certainly the difference would be marked in cases occurring in such material as presents itself at our City Hospital and in families such as the one referred to just now by Dr. Otis, from which he reported several cases of pleurisy, two with recovery. Certain pathologists, those of Vienna, for example, I believe, claim that the percentage of autopsies in which some tuberculous focus is not found, provided the examination be sufficiently minute and careful, is practically *nil;* in other words, that 97 or 98% of autopsies, minutely carried out, reveal the existence at some time or other of a tuberculous lesion.

Dr. William T. Councilman: Anatomically there was not very strong evidence in favor of the tuberculous character of all pleurisy. It is comparatively rare that a tuberculous pleurisy is the primary tuberculous lesion in the body and a point of departure for a further tuberculous infection. It cannot be said how frequently the pleurisies which leave behind traces of their presence in adhesions had been accompanied with effusion. With regard to the general frequency of tuberculosis at autopsy Dr. Councilman said that he did not regard it as too high an estimate to say that three-fourths of all individuals at autopsies had some tuberculous lesion in the body.

BOSTON SOCIETY OF PSYCHIATRY AND NEUROLOGY.

J. W. COURTNEY, M.D., SECRETARY.

(Concluded from No. 7, p. 192.)

Dr. Magrath: Dr. Walton pleads for a greater precision, which, it seems to me, would be very greatly advanced by the use of the terms deviation and deviate to designate conditions of departure from the type in any direction. The condition of degeneration in cells and in tissues may be a normal condition. A degeneration of the omphalomesenteric artery, changes in blood vessels which accompany the alteration in circulation from the fetal to the adult type, is accompanied by degeneration of tissues; therefore, degeneration in this morphological sense is normal. The absence of degeneration, persistence of what for the fetal conditions is normal, would be a deviation of type, and in itself would be an atypical condition, in that sense a degeneration, as departing from the normal. I feel grateful to Dr. Walton for making this plea for greater precision and suggesting the means to the end.

Dr. Sawin: I am very glad to be present because of the interest I feel in the kind of work

done by the members of this society. I was particularly interested in Dr. Walton's paper, and it seems to me there is a vast amount of material in this state in connection with the penal institutions that is not utilized, particularly in the state prison and the reformatory at Concord. It seems to me, also, that some members of your society ought to make efforts either to get on the commission or have some connection with those institutions to study the material. While I was at the state prison seven years I was more or less interested in the work, but did not feel competent to pursue the study as I should.

At a recent conference on charities, at Buffalo, N. Y., Dr. Laub of Dannemora claimed that 20% of the inmates of state prisons are insane, and Dr. Robertson of Elmira Reformatory recommended the addition of an experienced alienist to the prison department, to regularly visit each penal institution, and thus minimize dangers to society by transfer to insane hospitals of criminals whose terms are about to expire.

DR. W. E. PAUL: The consideration of the word deviate as presented by Dr. Walton will serve one good purpose in that it will clear in one's mind the significance of degeneracy. That a new term is needed as an equivalent of degeneracy may be questioned. The uncertainties as to the meaning of degeneracy and the varying use and ambiguities of the term should influence us to fix more firmly and clearly the meanings the word should convey, rather than be accepted as a demand or justification for a new word.

It seems to me that at present any use of the term degenerate carries with it some reference to mental qualities always in the nature of a blemish. The long list of anatomical deviations from the ideal normal called stigmata should be observed and described; but one should not at once assume that the individual thus marked is inefficient or peculiar physically.

I do not believe Dr. Walton can assure us that deviate, if adopted, would escape all the difficulties attending the use of degenerate. Perhaps all this discussion really represents a call for more terms, or subheadings, in the general subject, a better classification and a more systematic arrangement of all the branches included under degeneracy. Deviate and deviation would, it seems to me, be admirable terms to apply to anatomical variations.

DR. W. E. FERNALD: It seems to me a change in the nomenclature, as Dr. Walton suggests, would tend to clear the air somewhat in that it would help us to recognize that certain variations in type are normal. I was consulted, a few days ago, by an educated woman who came to see me in great distress because she had discovered that her eleven-year-old daughter had a Darwinian tubercle. She had consulted various physicians and was in a distressed condition. It seems to me that we forget that every individual is the sum of his ancestors and that the tendency for nature to seek a common denominator explains some of the variations from the normal type.

DR. J. W. COURTNEY: I have long been interested in the subject which Dr. Walton has so convincingly presented to the society this evening. At the present time it may be said that the popular conception of the term degenerate has been attained largely through the propaganda of pseudo-science and the yellow press. With the idea of doing something toward establishing a more rational view of the matter I some time ago wrote the following for a semi-popular medical work: "At the present day we frequently hear the term 'born degenerate' used to designate some unfortunate who happens to be the possessor of a high-arched palate, misshapen ears or an asymmetric skull, and who, under the stress of circumstances, betrays some mental or moral obliquity. The argument is that nature, while inflicting upon this individual outward stigmata of her freakishness, has been equally unkind in the matter of moral and intellectual endowments, and that he, in sinning against well-recognized laws, is simply the victim of his own vicious organism. To argue thus is fallacious in the extreme, for it throws a most unwarrantable burden upon nature, and leaves absolutely nothing to the account of two factors which are of vast importance in determining the mental, moral and social status of the individual — namely, education and environment. In proof of this one has only to seek in the circle of his own acquaintances. This all leads, however, to the matter of heredity and its influence upon a person's nervous and mental welfare. Upon this point may be quoted the following admirable statement of the facts in the case by Dr. James J. Putnam: 'Fortunately for the educational outlook, the evidence has begun to accumulate that a morbid inheritance is not the inevitably crushing and baneful thing that it has been thought. We come into the world, each one a being of limited capacity, but in other respects free to become what circumstances make us, and responsible, to the extent of our capacity, for our lot. We bring no ticket-of-leave which stamps us as drunkards or maniacs on probation, but we do bear, in the histories of our ancestors, a certificate that hints by what efforts and by what avoidances we can make ourselves reasonable successes in our respective lines. There is no original sin, and not even, as it seems to me, original propensity, but only original capacity and original limitation, and even limitation is only another name for latent capacity.'"

DR. P. C. KNAPP: I think we would all agree that there is something in degeneracy; that a degenerate as depicted by Morel is a being who cannot be exactly described or classified, yet whose existence can be in a measure recognized; just as we would all agree that there is something in physiognomy, without accepting all the doctrines of Lavater, and that there is something significant in the shape or form of the hand, without going into the extravagances of Des-

barrolles; but the work done by many pseudo-scientific men in describing the so-called stigmata of degeneracy seems extravagant, while the incessant measurings to get the quarter or half-inch deviation from the accepted standard suggest Cowper's lines:

> "The toil of dropping buckets into empty wells
> And growing old with drawing nothing up."

I think, therefore, Dr. Walton has done a service in bringing forward this substitute, which is open to the objection that it is too general. We are all deviates, and the perfect type is one which does not exist. It is simply a question of averages, and the departure from the average, whether in height or weight or color, is not in any way to be regarded as an indication of disease or abnormality. Some of the stigmata of degeneration which Lombroso, Peterson and others have enumerated may fairly be regarded as such stigmata; they are the indication of a morbid heredity, a decline of the individual; but others may be due to acquired disease in the individual, others still to mere mechanical influences, as the amputation of the hand in utero. An abnormally shaped palate which was due to some acquired disease in the nasal tract would count as a stigma of degeneration as much as some marked moral or physical perversion which was an actual indication of hereditary taint. I think Dr. Walton's term is very much more appropriate, but it is open to the objection of being too general.

Dr. Walton, in closing: It is not proposed that the word degeneration be abandoned, but that its use be curtailed. It should not be supplanted, but supplemented. Only such stigmata as are undoubtedly deteriorative should be called stigmata of degeneration, and the word degenerate should be applied only to individuals in whom the signs of deviation are of such character or in such number as really to indicate degeneracy, mental, moral or physical. All individuals deviate from the average normal, and if the proposed nomenclature be accepted, a person might be said, for example, to be a deviate but not sufficiently to be placed in the degenerate class.

Recent Literature.

Physical Diagnosis of Diseases of the Chest. By Richard C. Cabot, M.D., Physician to Out-Patients, Massachusetts General Hospital, Assistant in Clinical Medicine, Harvard Medical School. Second Revised Edition. Wm. Wood & Co.

Successive editions of a book may be said to justify themselves in the demand to which they furnish the response, and this manual, surely, in quality or presentation of subject matter, needs no higher compliment. The revision, however, has not been made with that care that might reasonably have been demanded. Obvious errors in proofreading, an occasional crudity of diction, a carelessly compiled index, are all details which, even if excusable in a hastily prepared first edition, are certainly not to be tolerated in the second. Thus, for example, pneumohydrothorax has become pneumoserothorax, but figures also as seropneumothorax and sero-pneumothorax, while to hydrothorax has been granted no variety from its old nomenclature. Those of the illustrations which are reproductions of photographs or radiographs are either poorly or atrociously executed, and there are several which, good or bad, might well have been spared.

Of new matter the only essential addition is a short and comprehensive description of apparatus and methods used in the testing of blood tension.

A Textbook of Legal Medicine and Toxicology. Edited by Frederick Peterson, M.D., Chief of Clinic, Nervous Department of the College of Physicians and Surgeons, New York; and Walter S. Haines, M.D., Professor of Chemistry, Pharmacy and Toxicology, Rush Medical College, in affiliation with the University of Chicago. Two volumes of about pp. 750 each. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

We have already commented in our issue for Sept. 3, 1903, upon this work on Legal Medicine and Toxicology as a whole, with special reference to the first volume, which at that time had alone appeared. Twenty-four contributors write for the second volume, and, as stated in the preface, their papers have been inserted practically without editorial change, which, with its evident possibilities of repetition and confusion, the authors regard as the wiser plan, inasmuch as individual responsibility more than compensates for such possible defects.

The second volume is comprised in two parts, the first of which is concerned largely with the medico-legal aspects of sexual matters. Part II takes up the general questions of toxicology as applied to medico-legal investigation, a matter which has been of increasing importance during the past few years. The list of authors of the various articles is a guarantee of the carefulness of the work. A section of the book which should be of much value, and so far as we know is unique in the form here presented, is that concerning laws relating to the insane, being a digest of the statutes of all the states and territories and of the District of Columbia relating to the commitment, care and custody of the insane. To have this information, ordinarily somewhat difficult to obtain in concise form, brought within the limits of about one hundred pages cannot fail to be extremely useful.

This volume, like its predecessor, is adequately illustrated with colored plates where necessary, as well as with the ordinary text cuts. We have no doubt the volumes will fill the place for which they are designed, namely, to provide for physicians and lawyers "a fairly comprehensive survey of forensic medicine in moderate compass."

THE BOSTON

Medical and Surgical Journal.

THURSDAY, FEBRUARY 25, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

PREMATURE BURIAL.

A BILL has been presented to the Massachusetts Legislature, now in session, entitled an "Act to restore Life, and to prevent Premature Encoffinment, Burial, or Cremation," the provisions of which are of sufficient interest to the medical profession to warrant careful consideration. The act reads as follows:

SECTION 1. That no person shall place the body of any human being in a coffin, casket or other receptacle by which air or light is excluded, or by which free movement is prevented, or bury or cremate such body except after a certificate of death as hereinafter provided.

SECTION 2. Whenever any person in any city or town apparently deceases, the board of health of said city or town, or the selectmen of such town, if no board of health exists, shall within six hours of such event being known be informed of such apparent death by any person or persons having the body in charge.

SECTION 3. As soon as is possible after such information the board of health, or said selectmen of such city or town in which such apparent death occurred, shall cause an examination of such body to be made to determine whether death is real or only apparent, and certification of the fact of death shall not be made until the following facts are established by actual tests, wherever possible, viz.: One, Heart sounds entirely absent, the test being by the stethoscope. Two, Respiratory sounds entirely absent. Three, Temperature of the mouth same as that of surrounding air. Four, A bright needle plunged into the body of the biceps muscle, left there, shows no sign of oxidation. Five, Intermittent shocks of electricity at different tensions passed by needles into various muscles and groups of muscles give no indication whatever of irritability. Six, Fillet test applied to veins of the arm causes no filling of veins on distal side of fillet. Seven, Opening of vein shows the blood to have undergone coagulation. Eight, Subcutaneous injection of ammonia causes a dirty brown stain indicative of dissolution. Nine, Careful movements of the lower jaw and of lower extremities and of occipito-frontalis indicates the presence of rigor mortis. Ten, Scarlet line (diaphanous test) is absent. Eleven, Decomposition has set in. And provided, further, that, if there is an absence of any of the signs of death except decomposition, all known means of resuscitation shall be tried while such signs are absent.

SECTION 4. The tests provided for in Section 3 shall be made by not less than two doctors of medicine in person, who shall have lawfully received the degree of M.D., one of whom shall be appointed by the board of health, and said doctors shall certify to the several tests made with the result of each test.

SECTION 5. No provision of this act shall be construed to prevent any means being used by any person to restore life to the supposed dead body.

SECTION 6. Every city and town shall provide suitable rooms for the carrying out of the provisions of this act, wherein tests may be made. Said rooms shall contain conveniences for resuscitation of bodies and for funeral services: *provided, however*, that the provisions of this act shall preferably be carried out in the domicile of the supposed deceased, his relatives and friends; but in no case shall any provision of this act be omitted. The expense of said rooms shall be included in the annual expenses of the city or town and provided for in the annual appropriation of money for city and town purposes.

SECTION 7. The fee for the services provided for in Section 3 shall be fair and reasonable, and shall be fixed by the board of health and be at the expense of the city or town.

SECTION 8. Any violation of this act on the part of any person responsible therefor shall be deemed a crime, and shall be punished by a fine of one thousand dollars or by imprisonment for one year, or by both such fine and imprisonment.

SECTION 9. All laws or parts of laws inconsistent with this act are hereby repealed in so far as they apply to this act, but no further.

SECTION 10. Copies of this act shall be conspicuously posted in all cities and towns of this Commonwealth by their respective boards of health.

The peculiarity of some of the foregoing provisions is worthy of comment. If a householder, or any one having charge of the body of a deceased person, does not inform the board of health of a town as to the fact of such death within six hours after its occurrence, he is liable to a fine of $1,000, or imprisonment for one year, or both fine and imprisonment. Ignorance of

law is no excuse for violation, but, nevertheless, the penalty here seems severe.

According to the terms of Sections 3 and 4 two physicians must see each dead body, armed with the following paraphernalia — stethoscopes, thermometers, bright needles, electric batteries, fillets, lancets and syringes, and if any one of the eleven tests or signs named in Section 2 do not respond, then the physicians must continue "all known means of resuscitation, while such signs are absent." If the attending medical men become weary and cease their exertions, a fine of $1,000 awaits them.

The expense of providing rooms for such examination as is required by this act is to be borne by the cities and towns. This, however, is but a small portion of the expense of carrying out the provisions of the act. A "fair and reasonable fee," such as is named in Section 7, for making all of the eleven tests described in Section 3 and of keeping oneself supplied with all the necessary apparatus for making them, should not be less than $5 for each physician or $10 for the two, and this would entail upon the cities and towns a new tax of about a half-million dollars annually, since the yearly number of deaths is about 50,000.

The demand for such legislation arises from the morbid fear which some people have of being buried alive, an occurrence which is less likely to happen than that of being struck by lightning. Without presuming to doubt the rare occurrence of such an event, we can hardly deem it reasonable to enact such legislation as is here demanded for its prevention.

Professor Brouardel, a high modern authority on medical jurisprudence and director of the Paris Morgue, admits the possibility of premature burial in rare instances,[1] but adds, except a single case which he cites: "None of the cases as such are very conclusive. The newspapers describe them, but no medical man has been a witness. When I read of such a case in a newspaper, I make an inquiry, as other physicians have done. I write to the mayor or to the health officer and ask him if the facts are genuine. The reply I am wont to receive is that the story is quite unknown in that part of the country whence it is supposed to have come, or that the person mentioned is not dead, and has not been placed in a coffin."

In several cities of southern Germany, establishments have existed for many years (since 1821 in Munich and for more than a century in Weimar) where every body of a deceased person is exposed for at least two days. The writer visited two of the cemeteries in Munich, a few years since, where these reception houses exist, one near the center of the city, another outside the city across the river Isar, and learned that out of the many hundreds of thousands of corpses that have been brought to them during these many years, not one has ever shown signs of life.

Most of the published statements upon this subject consist of a curious collection of sensational stories copied from public newspapers, traditions, fables and falsities, with here and there a grain of wheat among the chaff. Considered as additions to science they have but little value.

Looking at the subject, however, from the standpoint of protection from crime, there is room for improved legislation, such as was once asked for by members of the Massachusetts Medical Society. It is desirable that the small percentage of deaths which occur without the cognizance of an attending physician, but are not apparently due to violence, should receive the attention of some medical official clothed with authority to issue a certificate of death. For this purpose, however, it would not be necessary to enact legislation of so cumbrous and stringent a character as that required by the provisions of Senate Document 69.

[1] La Mort, et la Mort Subite, p. 35.

A MEDICAL MEMBER OF THE PANAMA CANAL COMMISSION.

The Committee on Medical Legislation of the American Medical Association, consisting of Drs. C. A. L. Reed of Cincinnati, Wm. L. Rodman of Philadelphia and Wm. H. Welch of Baltimore, is vigorously urging the appointment of a representative of the medical profession as a member of the Panama Canal Commission. The National Legislative Council of the Association, consisting of the above committee and one representative from each state medical association, at its regular session held in Washington, Feb. 11 last, adopted the following:

Whereas, a well-known unsanitary condition prevails on the Isthmus of Panama, as shown by the large percentage of sickness and death among the laborers engaged in the previous work on the Panama Canal, and in view of the fact that the successful prosecution of future work on the canal must largely depend upon the sanitary administration, which includes the prevention of sickness and the saving of the lives of the laborers, quite as much as upon the solution of the great engineering problem:

Resolved: That a representative of the medical profession who is an authority upon the advanced methods of investigating the causes and of the prevention of disease should be appointed a member of the Panama Canal Commission, that he may have authority to protect the health and thereby save the lives of persons engaged to work on the proposed Panama Canal.

A letter has been addressed to the President of the United States by the Committee of Medical Legislation enclosing this resolution, advocating the appointment of a medical member of the Panama Canal Commission, and suggesting Col. W. C. Gorgas of the United States army for the place. The committee also asks for a personal hearing before the commissioners are finally selected.

The commission is to consist of seven members, of whom four, under the law, must be engineers. As we write, it is generally understood that a majority of the members have been already selected. The Congress very properly recognized that engineering problems are the essential ones to be solved at the Isthmus, and as properly that the necessary technical ability to be efficient should be clothed with full authority. If the sanitary problems connected with the construction of the canal are also of prime importance the same consideration applies in a measure to them. Past experience has shown that the sanitary problems at the Isthmus, if secondary in any degree to the engineering problems, are certainly not far behind these latter in importance. We have no desire to exaggerate the unhealthfulness of the Isthmus or of any part of Central America. It is doubtless as untrue that the whole line of the canal is one unbroken zone of plague as that it is a region foreordained as the white man's sanitarium. Rather favorable statistics have been quoted as to the percentage of sickness and mortality rates among employees in recent years and working at a higher altitude. However this may be, we think the unprejudiced and those most competent to judge will agree that the construction of this canal at that site cannot be carried to a satisfactory and creditable conclusion without a constant, an intelligent and forceful control of all hygienic and sanitary considerations and details. It is not enough that good advice should be available; there should also be prompt and efficient execution.

In suggesting the name of Colonel Gorgas for the commission the committee of the American Medical Association has selected a person well qualified to secure the realization of these general considerations. His work as sanitary officer of Havana in clearing that city of yellow fever is well known to the medical profession at large. He is no less favorably associated with recent investigations in regard to malaria. He shared with Maj. Walter Reed the honor of a recommendation by the Secretary of War, in his report for 1902, for special recognition of services from the government of the United States. Colonel Gorgas was born in Alabama, and is about fifty years of age. Much of his military service has been at stations on the Gulf coast. He is at present stationed at Governor's Island, New York Harbor, as chief surgeon of the Department of the East.

Colonel Gorgas has theoretical knowledge, technical skill and practical experience in sanitary matters; moreover, these are combined with a knowledge of men and affairs and a tried administrative ability. This combination of characteristics would seem to constitute what is required of at least one member of the canal commission.

In addition to safeguarding the health of employees, such a commissioner would find in the sphere of his functions such problems as securing a better understanding than now exists of the etiology of Chagres fever, and the gradual establishment of such conditions on the Isthmus as would give guarantees against its becoming later, when the canal is open to traffic, a distributing center to the eastward of such a disease as yellow fever, and to the westward of cholera and plague.

Since the above was written and in type, the commission has been made up without a medical representative. Whatever method may be favored for securing the sanitary requirements of the situation, we see no occasion to change our statement. The disappointment of the medical profession that no sanitarian has been placed on the commission may be mitigated, though not removed, by the report that the services of Colonel Gorgas are likely to be retained in an advisory capacity.

MEDICAL NOTES.

AMERICAN GYNECOLOGY. — The January number of *American Gynecology* was destroyed in the fire which recently visited Baltimore.

BURNING OF AN INSANE HOSPITAL. — It is reported that the Racine, Wis., County Hospital Asylum was burned on the night of Feb. 19.

There were at the time under treatment 133 patients, who were taken from the building in safety.

A Centenarian. — Miss Clarissa Merrill died in Utica, N. Y., Feb. 28, in her one hundred and first year. She retained her mental power essentially unimpaired up to the end of her life.

In Honor of Dr. D. B. St. John Roosa. — A dinner was given at Delmonico's, New York, Tuesday evening, March the first, in honor of Dr. D. B. St. John Roosa and to commemorate the twenty-one years since the inauguration of post-graduate medical instruction in this country. Dr. William Osler of Baltimore presided.

Printers and Editors. — The following statement, taken from the columns of our contemporary, the *Journal of the American Medical Association*, expresses our present point of view: "That Chicago publications are not the only ones that are embarrassed sometimes by strikes in the mechanical department, is evidenced by the apology for lateness of issue which the *Boston Medical and Surgical Journal* gives in a recent number. Our contemporary has our sympathy, as has also the *Journal of Medical Research*, which likewise has the misfortune (we use the word only in its application to the existing delay) to be issued in Boston. A card announces that the *Index Medicus* is also a sufferer, the annual indexes for 1903 being still unfinished. We wish our Boston friends speedy release from their handicap. Our sympathy is born of experience."

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, Feb. 24, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 31, scarlatina 29, typhoid fever 6, measles 214, smallpox 0.

The Usual Antivivisection Bill. — Hearings have been held this week (March 4) before a committee of the Massachusetts Legislature on the usual bill for the restriction of vivisection.

Typhoid Fever in Franklin, N. H. — It is reported from Franklin, N. H., that a number of cases of typhoid fever have appeared in that city, supposed to be due to the use of river water for household purposes. This was necessitated by a temporary deficiency in the regular water supply.

NEW YORK.

A Bill to Legalize "Optometry." — Much protest has been evoked by a bill recently introduced into the Legislature designed to give legal status to the business of opticians ("optometry," so-called) as a profession separate and distinct from other branches of medical science, and the State Medical Society, working through the sixty county societies represented in it, is conducting a vigorous campaign against the measure. Three years ago a somewhat similar movement was made in the Legislature of Massachusetts.

The New York Eye and Ear Infirmary. — It is announced that the New York Eye and Ear Infirmary has not been able to meet expenses, with the unfortunate result that there is now a possibility of its entire discontinuance. It is to be hoped, however, that some less radical course may suffice either through a certain restriction of the hospital work or, what is much more to be desired, through the increased financial support from public-spirited citizens. The institution is an old one; it has done admirable work in the past; and there is an increasing need of its services to the poor in the future.

Miscellany.

MEDICAL UNION NUMBER SIX.[1]

"Medical Union Number Six takes for a theme the growing arrogance and unbridled excesses of labor unions. It casts a long look ahead, and, in the form of fiction, describes in biting satire a condition of things that might be the logical outcome of unrestrained labor unionism carried to the extreme toward which its dominant impulse of to-day is directing it. The book is at once a protest and a warning.

"The scene of the story is laid in New York, in the middle of the twentieth century, when the country has become completely unionized. Even the ministers and doctors are banded together in unions. One, Dr. Schneider, joins Medical Union Number Six, and the story presents the theories, principles, working methods and rigid rules of that organization as it is controlled by its riding delegates, and relates the experiences of the doctor under the new order of things. It appears that the union doctors work only six hours a day, and one man is permitted only to treat ailments in certain designated parts of the body. Patients must take such doctors as may be sent to them from union headquarters, and no doctor is allowed to work beyond the prescribed hours for his tour of duty, or to treat anything outside his specified field of operation — the throat, the chest, the extrem-

[1] Medical Union Number Six. By William Harvey King. 16 mo. 60 pp. The Monograph Press, 25 West Broadway, New York.

ities, etc. — no matter how serious a case may be or what emergency may arise. Non-union or unfaithful doctors are promptly killed, and union undertakers and clergymen refuse their services for those who are so heedless as to die in the hands of a non-union doctor.

"A tragedy ends the story. Because Dr. Schneider lets a patient die rather than transcend a union rule there is a popular uprising against the Medical Union. The physicians go on a strike, but the people hold out, and finally the union, in order to bring the public to its senses, causes an outbreak of the bubonic plague, which devastates the country. Then the people humbly sue for relief, and the strike is declared off, after millions of men, women and children have died, and towns and cities have been wiped out. 'Of course,' the story says in conclusion, 'there was nothing left for the doctors, but the principles of the union were maintained.'

"The work is not pretentious, either in size or in plot, but into its pages are crowded a great deal that is food for serious thought. Many of the ideas, as set forth, are, of course, intentionally extravagant, as befits satire, but, after all, they are not altogether so extreme as might seem at first blush. Almost a parallel for some of them may be found in recent union disturbances in Chicago, when churches and funerals were mobbed, and the dead with difficulty were buried, and in other affairs in Connecticut, where strikers stopped funerals and would not allow graves to be dug.

"A vein of humor, grim though it be, pervades the book, but underlying that is a serious purpose that marks the real aim and worth of the work. Its hits are so palpable and so merciless that they draw blood, and are not likely to be very much relished by those at whom they are aimed."

The above is an abstract of a little brochure just received. It has an especial interest, as the JOURNAL is at present suffering from a strike of compositors and pressmen, the latter going out in sympathy with the former, although contrary to a contract of their own union. Perhaps these pages may meet the attention of strikers as well as those of the stricken. It is a very fair *reductio ad absurdum*.

Correspondence.

"ARRESTED TUBERCULOSIS."

SHOULD UNPROVED CASES BE THUS RECORDED?

BOSTON, Feb. 23, 1904.

MR. EDITOR: At this time when Boston physicians are specially interested in the control of Tuberculosis, the statistics of institutions for its relief are of unusual importance. May I therefore be allowed a few words in the JOURNAL on this subject?

A report has recently been published on "Arrested Tuberculosis. Subsequent histories of 79 arrested cases treated at the Sharon Sanitarium from 1891 to 1902." [1] In this paper the term "arrested" is explained by Dr. V. Y. Bowditch as including "all those cases in which abnormal outward symptoms have disappeared." He says: "Seventy-nine of these 164 cases were recorded as 'arrested,' a percentage of 48.17+ of all the phthisical cases," and still further, "Of these 79 cases, . . . 12, or 15.2%, have died since leaving the institution, after varying intervals of comparative health."

An inspection of the table of the 79 cases of arrested Tuberculosis shows that the diagnosis of phthisis was not confirmed by the presence of Tubercle bacilli or the use of Tuberculin in more than one-half of the cases (41 out of 78).[2] In justification of their inclusion it is said that "only those cases have been taken which experience teaches us usually develop later more definite signs of disease under unfavorable conditions." Not only at Sharon, but also in other sanitaria, both in this country and abroad, Tubercle bacilli are found in the sputum in only about one-half the cases of incipient Tuberculosis reported as cured [3]; and in the remaining cases the use of Tuberculin as a routine is not mentioned. The cases at Sharon, therefore, may fairly be taken as an example of those from other similar sanitaria.

An inspection of the physical signs in these 41 cases shows, as might be expected in incipient Tuberculosis, that practically all of them had very slight changes in one or both apices, such as suggestive modification in the respiration, localized râles or slight deviations from the normal percussion note, singly or combined. These physical signs in conjunction with the history of the cases suggest, but it does not seem to me prove, the existence of pulmonary Tuberculosis. Within the past few years it has been recognized that other bacterial infections of the respiratory tract may closely resemble Tuberculosis, and the history of the case and the physical examination cannot with certainty be relied on for diagnosis. The Tuberculin injection in cases suspected of pulmonary Tuberculosis without Tubercle bacilli in the sputum is subject to the error of a reaction in a certain proportion of apparently healthy individuals. The absence of such a reaction, however, in patients with pulmonary symptoms without Tubercle bacilli in the sputum excludes Tuberculosis as conclusively as our present means of diagnosis allows. Prof. R. Koch,[4] in his address at the British Congress on Tuberculosis in 1901, speaking from an experience of over three thousand cases in which Tuberculin had been used under his supervision, said: "The Tuberculin test is of special value in judging of catarrh of the apex pulmonis without Tubercle bacilli in the sputum, especially when influenza is prevalent, because then cases pretty often occur which to the eye of the clinical observer exactly resemble Tuberculosis but are not that. Among our numerous patients suffering from catarrh of the apex pulmonis there were almost 15% in whom no reaction took place; and in all the cases which could be observed long enough, the further course of the disease confirmed our opinion that they were not cases of Tuberculosis."

The validity of a reaction after the use of Tuberculin for the diagnosis of pulmonary Tuberculosis in any series is questionable when we consider the proportion of apparently healthy individuals who have been shown to have latent Tubercular foci. MacFadyen,[5] for example, found Tubercle bacilli by animal inoculation in the mesenteric glands in 25% of 20 cases unsuspected of Tuberculosis. P. Baumgarten,[6] excluding cases with Tuberculosis as a cause of death, said that he had found latent Tuber-

[1] Journ. Am. Med. Ass., Nov. 14, 1903.

[2] One case (No. 49) is omitted because there are no data concerning the presence or absence of Tubercle bacilli or the Tuberculin reaction.

[3] Reports from different sanitaria are very meagre concerning Tubercle bacilli or Tuberculin reaction in apparently cured cases. In some no mention of either is made. Among those giving data are:

Brown (L.): Adirondack Cottage Sanitarium. J. Am. Med. Ass., Feb. 21, 1903. In 76 incipient cases, T. B. found in 26%.

Elliott: Am. Med., Phila., 1903, v, 294-6. Of 96 cases apparently cured, T. B. found in 64%.

Pickert: Zeit. f. Tuberculose, 1902, Bd. iv. Collected statistics from nine sanitaria, T. B. found in 45.7%.

Engelmann: Results of Open-Air Treatment of Consumption, Berlin, 1901, p. 12. Of 393 patients in the first stage from five sanitaria, T. B found in only 25.4%.

[4] Trans. Brit. Cong. on Tuberculosis, 1901, p. 93.

[5] Brit. Med. Journ., 1903, ii, 129.

[6] Volkmann's Vortrige, 218.

cular foci in about one-third to one-fourth of his autopsies. His results have been abundantly confirmed, and explain the proportion of apparently normal individuals who react to Tuberculin.

The recognition of Tubercle bacilli in the sputum, therefore, must be regarded as the only infallible indication of Tuberculosis of the respiratory tract.

In the work at the Massachusetts General Hospital I have been impressed with the constant prevalence of influenza and its close resemblance in many cases to pulmonary Tuberculosis, not only in apex catarrh, but also in signs of persistent pulmonary solidification. These cases have shown influenza bacilli in practically pure culture in the purulent and at times bloody sputum and Tubercle bacilli have been absent after careful and repeated search. In some of my earlier work the mistake was made of not subjecting all such cases to Tuberculin, but in later cases there has been no reaction.

These observations have led to the belief that some at least of the incipient cases, without Tubercle bacilli, recorded as "arrested" in this and other sanitaria may not be Tuberculosis. Unlike Tuberculosis these cases do not tend toward a fatal termination, but rather remain stationary or slowly progress toward recovery. If such cases, therefore, are included among the 41 unproved cases in the Sharon report, their course should be more favorable than that of the 37 remaining cases with positive evidence of Tuberculosis. On tabulating the cases into two classes, according to the presence or absence of proof of Tuberculosis, there is much to confirm this possibility.

CLASS I.[7]

	With T. B. or Tub'l'n. react.	Excell.	Good	Fair	Poor	Dead	?	Total	Mortality
		2	21	1	1	9	3	37	24%

CLASS II.[8]

Without T. B. and no mention of Tub. react.	0	34[9]	3	0	3	1	41	7%

The cases in both classes are much alike in physical examination, but a mortality more than three times as great among the proved cases (Class I) strongly suggests other organisms than Tubercle bacilli as the cause in some at least of the unproved cases (Class II). This difference in the mortality is even more striking when one considers the three fatal cases in Class II. One of these (No. 45) had "mitral disease" and another (No. 52) had been "without cough for some time; died suddenly." The more favorable result in these unproved cases obviously raises the percentage of those with arrested disease.

A more favorable result in cases without Tubercle bacilli in the sputum is shown not only in the Sharon series but also in the statistics of other sanitaria. It is usually ascribed to treatment in the very inception of the disease, which is manifestly of great importance. Brown,[10] speaking of the results in the Adirondack Cottage Sanitarium, said that "when the diagnosis was made before Tubercle bacilli were found in the sputum before ulceration had begun, the chances for recovery were at least twice as good and on the whole seemed many times as good." What proof have we, however, that the symptoms in such cases are not due to infection with other organisms?

The great value of the sanitarium treatment of Tuberculosis is beyond question and is demonstrated by an "Excellent" or "Good" result in 23 of the 37 cases of proved Tuberculosis in the Sharon report. It seems to me, however, an error in classification in this and other sanitaria to include unproved cases among those with "Arrested Tuberculosis."

Truly yours,

FREDERICK T. LORD, M.D.

[7] Four cases (Nos. 21, 74, 75, 79) though recorded in the table as negative for T. B. are included in Class I, No. 21 because of the finding of T. B. later, the others because of positive Tuberculin reaction.

[8] In one case in the series the examiner appears doubtful of the presence of Tubercle bacilli (No. 48 + ?), in another of their absence (No. 29: 0 ?). Both of these cases are placed in Class II.

[9] One case (No. 19) is classed as "Good," as this is the condition mentioned under "Remarks."

[10] Brown (L.): Loc. cit.

DELAYED PUBLICATION.—The continued strike among printers and pressmen is responsible for delays in issuing the JOURNAL.

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR SURGERY. — A meeting of this section will be held at the Medical Library on Wednesday evening, March 2, at 8.15 o'clock. There will be no formal paper read, but the members are invited to discuss the Surgical Treatment of Hypertrophy of the Prostate. Members who cannot attend the meeting are requested to send to the secretary brief reports of any cases (particularly the unsuccessful ones) illustrating special points of interest in relation to this subject.

E. A. CODMAN, M.D., Secretary.
104 Mt. Vernon St.

MEDICAL SOCIETY OF THE MISSOURI VALLEY. — The spring meeting of this association will be held in Lincoln, Neb., March 24 and 25, under the presidency of Dr. A. D. Wilkinson.

CHARLES WOOD FASSETT, M.D., Secretary.

AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION. — As heretofore announced the American Medico-Psychological Association will hold its next annual meeting in St. Louis, May 30 to June 3, inclusive, under the presidency of Dr. A. E. Macdonald of New York.

C. B. BURR, M.D., Secretary.

AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY. — The tenth annual meeting of the American Laryngological, Rhinological and Otological Society will be held in Chicago, Ill., May 30, 31 and June 1, 1904, under the presidency of Dr. Norval H. Pierce.

WENDELL C. PHILLIPS, M.D., Secretary.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—The regular meeting of the society will be held in Sprague Hall on Monday, March 14, at 8.15 P.M. Drs. George H. Monks and Charles Harrington will present short papers on the subject of "Some Weak Points in Surgical Asepsis." These papers will be discussed by Drs. F. B. Harrington, James G. Mumford, J. Bapst Blake, F. B. Lund, F. S. Newell and others. After the meeting there will be a social half-hour.

ARTHUR K. STONE, M.D., Secretary.
543 Boylston St.

LECTURES TO NURSES.

A COURSE of lectures is being given at the Boston Medical Library to the nurses and their friends. The first was by Dr. Paul Thorndike, Feb. 23, 1904: "The Private Nurse from an Educational Standpoint, Comparing the Past, Present and Future."

The other lectures arranged for are:

March 2, 1904, 8 P.M. Dr. John Lovett Morse, "Infant Nursing."

March 8, 1904, 4.30 P.M. Dr. E. Channing Stowell, "Children."

March 22, 1904, 8 P.M. Dr. A. K. Stone, "Tuberculosis," with lantern slides. The public are especially invited to this lecture, as the subject is of general interest.

ERRATUM.

WE beg leave to correct an unfortunate typographical error which occurred in our issue of Feb. 18. On page 196, second column, line 18, 53,389 (bottles) should read 159,072.

RECENT DEATHS.

WM. RANKIN, JR., M.D., a prominent specialist in diseases of the eye and ear in Newark, N. J., died on Feb. 26 at the age of fifty-six years. He was a graduate of Rutgers College and of the College of Physicians and Surgeons, New York. After receiving the degree of M.D. in 1871 he studied for a considerable time in Vienna. He was for many years attending physician to the Newark Charitable Eye and Ear Infirmary, and was also secretary of the old Newark Medical Library Association.

GUSTAV LIEBMANN, M.D., M.M.S.S., died in Boston, Feb. 20, 1904, aged seventy-one years.

JEFFERSON CUSHING GALLISON, M.D., M.M.S.S., died in Franklin, Feb. 22, 1904, aged sixty-three years.

PUBLIC HEALTH AND MARINE HOSPITAL SERVICE EXAMINATION.

WASHINGTON, D. C., Feb. 16, 1904.

A BOARD of officers will be convened to meet at the Bureau of Public Health and Marine Hospital Service, 3 B Street, S.E., Washington, D. C., Monday, April 4, 1904, at 10 o'clock A.M., for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health and Marine Hospital Service.

Candidates must be between twenty-two and thirty years of age, graduates of a reputable medical college, and must furnish testimonials from responsible persons as to their professional and moral character.

The following is the usual order of the examinations: (1) Physical. (2) Oral. (3) Written. (4) Clinical.

In addition to the physical examination, candidates are required to certify that they believe themselves free from any ailment which would disqualify them for service in any climate.

The examinations are chiefly in writing, and begin with a short autobiography of the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery and hygiene.

The oral examination includes subjects of preliminary education, history, literature and natural sciences.

The clinical examination is conducted at a hospital, and, when practicable, candidates are required to perform surgical operations on a cadaver.

Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur.

For further information, or for invitation to appear before the Board of Examiners, address,

SURGEON-GENERAL,
Public Health and Marine Hospital Service,
Washington, D. C.

THE RELATION OF SOME SPECIAL CAUSES TO THE DEVELOPMENT OF NEURASTHENIA.

BY ROBERT T. EDES, M.D., BOSTON.

The field of functional nervous disease grows narrower year by year, but there still remains much where no lesion is discoverable by the microscope, no microbe or toxin by the incubator or test tube, and where symptoms are not accompanied by enough of that ever-increasing group of stigmata to form any reasonable basis for a diagnosis of degeneration or, as rightly and forcibly suggested by Walton, are not sufficiently variant from the average structure to make it even probable that a departure in the downward direction from the normal function must exist.

All these may be suspected but are not yet proved. Observation, however, has in so many cases found causes of irritation or sources of fatigue distant from the organs apparently most affected that a systematic search for peripheral disorders or systemic poisoning is the logical and correct procedure for therapeutic purposes.

This search resulting, as it should do, so often in a success which furnishes strong evidence in favor of the dependence of psychic or general nervous derangements upon local irritations or special nervous drains, when applied to large numbers of cases has resulted in so many theories, each claimed by its advocates as almost exclusive, that they cannot easily all be true, certainly not to the extent of being each exclusive of the others.

Unfortunately, many of them were apparently formed upon the basis of some special group, and the deductions, legitimate as applied to this, have been carried too far and made to demand a forced agreement from others which do not belong there.

Each one of these may alone seem reasonable, is undoubtedly based upon more or less well-observed facts and may lead to important therapeutic results, and yet when brought into confrontation with others in the attempt to construct an orderly etiology the results are contradictory and confusing.

Each under the advocacy of an enthusiast is satisfactory to him and to the disciples who are sure to attach themselves to any novelty, but each as it is tested beyond the original group fails to cover the claim. We have advocated as potent and comprehensive causes for neurasthenia, for epilepsy, for the severe headaches and other pains which are by some considered typical of neurasthenia, and by others the preludes thereto, several more or less distinct conditions which have been claimed either as covering almost the entire field or else, what would be the very perfection of diagnosis and pathology if it could be true, a definite and reasonable cause corresponding to a special and well-defined symptom-complex related to, but not identical with, neurasthenia. Such are overwork and worry, lithemia, eyestrain of two kinds, sexual diseases and abuses of the sexual organs and abnormal sexual feelings, ovarian irritation, displacement of the abdominal viscera, to say nothing of the remoter consequences of too fine wheat flour and too coarse Indian meal.

Difference of opinion is often really difference of definition and nomenclature, and the discrepancies may often be at least much diminished by a mutual understanding of what is meant. The name "neurasthenia" is not infrequently used to cover any mere jumble of nervous symptoms which are quite distinctly not to be referred to any of the recognized organic nervous diseases and do not readily fall into any of the established categories of the functional. Hence it may mean anything from melancholia on the one side, when we use it to avoid hinting at anything like insanity, or, on the other hand, epilepsy, chorea, bad habits, bad temper, general debility, hypochondriasis, indolence and so on.

The description of Glenard, though inaccurate and misleading except so far as it applies to his exclusive theory, is certainly a vigorous one.

"Neurasthenia (névrosisme, névropathie, névrose protéiforme, maladie nerveuse, état nerveux, nervosité, fievre nerveuse, épuisement nerveux, surexcitation nerveuse, vapeurs, maladie vaporeuse névropathie cérébro-pneumogastrique, dyspepsie nerveuse, etc.) is a chronic affection, in which all the organs, all the apparatus, all the systems may suffer successively or together, where no local lesion can be found, an affection of which the diagnosis is not made until after the elimination of all distinct diseases, of which the prognosis is contingent on the result and demands the proof of time, and of which the treatment exhausts the patience of the patient and the physician. It is because no lesion has been found that we have agreed to say that there is none, and then because we cannot explain the symptoms that we have agreed to incriminate the nervous system. Neurasthenia is an arbitrary morbid entity."

It is possible, however, without straining the facts, to accept the view that neurasthenia is not merely a name to cover want of classification, but is a fairly well-defined condition, if not a distinct disease, and has a real pathology. It is necessary to do this if we wish to get any correct idea of its relation to its alleged causes.

Neurasthenia is a state of diminished energy of the nervous centers, especially the higher psychical, closely akin to ordinary fatigue, of which, indeed, it is an extreme development, but so extreme as to have become different in kind, that is, in incapacity for rapid restoration under favorable circumstances and in a time in some measure corresponding to that taken in its development.

The ordinary everyday expenditure of energy, be it small or great, should be restored also within the same time, or, if there be a little falling behind, the accumulating loss made good at somewhat longer intervals.

When this loss becomes too great to be made up easily and the strain goes on without relaxation the condition becomes neurasthenia, *i. e.*, the centers are no longer capable of rapid restoration even under favorable circumstances. What the limits are is a matter which varies immensely in different persons. There are those who are practically beyond the chances of neurastnenia, and there are others whom only a very slight excess, especially of emotional strain, brings dangerously near the line. Within these limits the mass of civilized mankind is found, each having his capacity for carrying his burden, which may or may not be reached according to circumstances, a capacity which again is capable of considerable modification according to the way in which the load is carried. It is in the proper adjustment of the strength to the load, the selection of the proper rhythm of work and rest so far as possible, that the prophylaxis of nervous exhaustion consists. It is upon learning how to do this after a first failure that anything like a permanent cure depends.

To use a morphological illustration which may or may not have an actual basis in fact, we know that the examination of ganglion cells by Hodge and others has shown visible changes, diminution of the chromophile bodies and shrinking of the nucleus, dependent upon ordinary fatigue. It is possible that nervous exhaustion may depend upon a process which is more permanent and more resembling degeneration, as actual dislocation of the nucleus, and atrophy resulting from using up of more than the hydrocarbon elements, and a resort to the complicated proteid components which go to make up the structure of the cell itself and which cannot be replaced at short notice.

There are many forms of insanity which do not imply any weakening of the central impulses, but often the contrary. It might happen in such that there would not be so much change visible as in ordinary fatigue, although of course in others the lesions of the neuron are not only extreme but irreparable.

To use another simile, fatigue is a temporary weakening of the battery from keeping the circuit open too long. Neurasthenia is a using up of the elements, destruction of the zincs. Insanity may or may not include these, but is essentially a disarrangement of the connections, burning out of fuses and short-circuiting between centers which are not arranged to work together.

We must look to experiment and observation to determine which centers, which groups of neurons or which faculties are chiefly affected and have lost their capacity to store energy rapidly enough to renew constant losses. While it is probable that all are so to some extent, the essential point which must be yielded before neurasthenia can be said to exist is that which controls all the rest, which determines the direction and intensity with which the psychic apparatus shall expend its energy, that is, the attention, will, active apperception. This function is invariably attended by a motor impulse and usually by some degree of actual motor activity,—attention to visual objects by muscular contraction under the influence of the oculomotorius and the ciliary muscle; perhaps, also, by more or less of the muscles of the neck and trunk; auditory attention by contraction of the tensor tympani and stapedius; ordinary sensation by contractions of the muscles of the fingers, toes or tongue; perhaps, also, of the trunkal muscles holding the body perfectly still.

It must be considered, also, that inhibition of certain motions, as in the act of listening or watching, is also a motor impulse, even if resulting in no visible or perceptible motion. It is negative only in the sense of being in the opposite direction and calls for a positive expenditure of energy. The fatigue of restraint is a matter of common observation.

If emotional excitement is involved we have the reaction of the muscles of organic life, the heart, the respiration, vasomotor apparatus or intestine. It is immaterial what the amount of work measured in foot-pounds may be. It is the amount of nervous force expended in keeping up the necessary tension which has the controlling influence -- the amount of psychic effort and not the muscular work done is the important factor and standard of fatigue. The amount of energy liberated in the ciliary muscle in the effort to focus a printed page, which is very often thoroughly fatiguing, is almost infinitesimally small compared with that involved in the movements of the great masses in the back and legs in walking, which may be kept up for hours with comparatively little. Even this latter kind, however, is subject to the same rule. Hurrying to catch a train is felt as greater fatigue than walking the same distance at a leisurely gait.

It may be possible for simple thinking, revery or dreaming, the uncontrolled association of ideas, to go on without the motor idea, but it is difficult to imagine anything like careful or purposive thinking without it. Certainly all having any practical end in view must involve much of such ideas.

The intensity of thought is developed by emotional stress and when intellection is kept up continuously and at a high tension the fact of itself argues emotional stress of some kind, such as ambition, affection, fear or conscience. Worry may be defined as continuous mental activity under emotional stress of a painful kind, traversing the same ground with weariful iteration because coming to no useful conclusion. Here fatigue is not in the least a measure of valuable mental labor performed, but only of the activity of the attention in keeping the mind fixed. It is a matter of the most common observation that the inexperienced accountant, for instance, is much more tired from a mistake in a simple column of figures than the mathematician who soars into the regions of the calculus and astronomy. The possibility of keeping the attention fixed varies immensely in different persons, as every teacher knows, and it can be greatly improved by training, which is and should be one

of the chief ends of school life. The teacher soon knows who are the patient plodders, who learn and learn well because they keep at it, and which are the bright ones, who learn perhaps but little unless they can see it at the first glance. The training of the child's attention should, however, be gradual. He is naturally incapable of long periods of work without great fatigue. Short periods of real work with frequent pauses may be gradually lengthened as he grows older.

Fatigue is first felt in the muscles, but at that point is capable of very rapid restoration, next at the motor center and finally, when continued and when accumulating under pressure, felt most strongly and most permanently at the centers of will and attention which keep the lower ones up to their work. If this view or something like it be accepted it is easy to see how such various causes as have been alleged, and which are all probably to a greater or less extent operative, may lead to almost identical results, modified, perhaps, according to the channels through which peripheral irritations reach the psychic centers or through which the resistances are offered to the motor discharge.

We may say that neurasthenia is a paresis of the attention and will, the result of long-continued overfatigue, which in its turn is the consequence of enforced and often unsuccessful overaction of some motor activity carried on under emotional stress.

Apparently the simplest, most obvious and most frequently assigned cause for neurasthenia is mental overwork and, in the cases of the young, overstudy. Much has been written on these subjects, many experiments of the amount of fatigue produced by the various school studies and many warnings given. In one sense overwork, that is, the overaction of certain nerve centers, is the *only* cause of neurasthenia, but in the more limited sense of overwork in business, profession or school it is of much narrower application. The ordinary everyday work of the breadwinner, the housekeeper or the scholar, even if covering many more hours than are considered desirable by physiologists or approved of by labor organizations, but coming to a definite end at the end of day, brings fatigue, perhaps even intense fatigue, but it is rarely to the degree which is not susceptible of rapid restoration, either day by day or with the addition of the holiday or vacation.

It is when it is enforced or added to by responsibility, anxiety, ambition and especially when even with these reinforcements it is doomed to constant failure, to hopeless and fruitless endeavor, the labors of Sisyphus and the Danaidæ, that it becomes a crushing burden to those not richly endowed either by birth or by education with adequate resistance, or who have not acquired sufficient prudence to resolutely refuse to carry more than they know they can struggle under. It is on the correct estimation of one's nervous power and the resolution not to go beyond it and in the selection of the rhythm of work, whether it be the steady daily task or the "spurt" and long rest, whichever is most suitable to the individual, that the prophylaxis of this form depends.

Even utter monotony, which seems at first sight to be a safeguard, and probably often is so as transferring the responsibility of conscious cerebration to a mere automatism, may in reality be more wearing than some forms of mental labor of higher order or calling for much more individual action. The exhaustion, however, comes not from the amount of mental labor, not from the actual cerebration, but from the fatigue of the will in forcing one's self to keep on in spite of want of interest, disgust and *ennui*.

The muscular fatigue from the action of a large number of muscles, which represents the maximum of expenditure of energy at a low tension, is never itself a cause of nervous breakdown, but as an accessory and additional cause when injudiciously taken as a relief from intense mental activity it is of some importance, as, for instance, in the case of breakdown in teachers of physical culture.

The relation between muscular and mental fatigue is shown by the observation first made by Mosso of the shortening of the fatigue curve lasting for many hours after the subject had been engaged in an examination. This is not true of everybody and it would not be difficult to suggest an explanation in the difference to which the feeling of responsibility was present in different cases.

On the other hand, every one knows that extreme muscular fatigue renders one incapable for a time of doing his best mental work, but mere muscular fatigue is very rapidly restored.

As regards overstudy in school so often talked of as the cause of breakdown in young people, I believe it is very seldom seen from genuine overwork. There may be a good deal of fatigue, but it is of the kind and degree which does not go beyond physiological limits and is capable of rapid restoration. The fatigue may interfere with proper exercise and sleep and in this way promote ill health and retard development so that it would be a contributor to the result, but there is almost certain to be in such cases something outside or else, perhaps not very infrequently, something in the way the task is attacked which transforms what should be an interested search for knowledge or a gradual training of attention into an eager and thoughtless race for distinction or an anxious struggle to avoid failure. These are quite as likely to oe seen among teachers as scholars and more among girls than boys.

When a young man or woman is heard of as completely broken down by overwork in college, it is safe to conclude or, rather, since it is not safe to conclude anytning in medicine from hearsay, there is generally reason to suspect that other causes have been at work than that which is intended for the public announcement.

The great development of institutions of higher education, especially among women, has not resulted in any increase of nervous diseases. The

neglect and indifference to this important subject which obtains among so large a part of the profession even here, but which is even more marked on the other side of the Atlantic, prove that it is a less common cause than Dr. Gould supposes, but yet one cannot help feeling that a highly educated class of men, quite as anxious to be abreast of the times as any Yankees, could not willfully shut their eyes to so easily tested and so practical facts.

The eyestrain heretofore spoken of is that of the ciliary muscle due to errors of refraction. This was the first brought forward, and now it seems again to occupy the first place, but in the meantime there has been an episode.

The want of balance of the extrinsic muscles has had as many and as disastrous consequences attributed to it as the ciliary. This, to which Dr. Gould assigns only a secondary and accidental importance and proposes to correct when present by prisms, strongly disapproving of muscle cutting, Stevens and Ranney treat exclusively by the latter method and speak contemptuously of glasses.

As regards severity of cases and completeness of relief the claims are far in advance of any of the refractionists. "Esophoria, hyperphoria and hypermetropia are the most common abnormal conditions encountered in cases of neuralgia, headache, epilepsy, chorea, insanity, nervous prostration and other severe types of chronic nervous disturbance."

Wilton and Carter say: "It is perhaps the extreme character of these views which has defeated their adoption, but is probably nearer the truth than the view that this factor need not be mentioned in the etiology of migraine or considered in its treatment." Ranney, however, claimed far more than headache.

It is in reference to this form of eyestrain that St. John remarks after the examination of a series of cases with this point in view: "For every eyestrain headache there are twenty from disordered stomach or liver, improper food, want of exercise or other irregularity in the domain of the general practitioner." Dr. Gould would probably claim this twenty as due to strain of the ciliary.

It has been remarked that no instance has yet been brought forward in which headaches have followed the use of other than the ocular muscles, but the principle upon which these ocular headaches depend has probably a wider application.

Hancock, referring to this remark, says: "While I fully admit that continual muscular exertion in general does not cause headache, I think it probable that excessive and continued contraction of any muscle supplied by cranial nerves would do so."

It seems to me that it would be more philosophical, instead of limiting the exception anatomically, to have put it that continued use of muscles at a high grade of tension and attention was the cause of the headache. The ciliary is the purest type of such a muscle and undoubtedly its overaction, and especially its action which accomplishes its object for a time and with much difficulty, is the cause of more headaches than that of any other one, but there is no reason why there cannot be an ear headache of the same character, although it is, of course, easier and safer to give up any attempt whatever at hearing than of seeing.

Blake has called attention — although not having his paper at hand I am not sure that he mentions headache as amongst the symptoms — to the fatigue which arises from a person with somewhat defective hearing trying to hear distinctly. It depends on three distinct efforts, of which only the first, the effort to hear, is referable to the ear. The second is the effort to supplement this failure by lip reading and the third the mental effort to fill the gaps left by the two senses.

The case of a neurasthenic girl who used to have headaches after reading, just as eyestrain cases do, is interesting. She had lost many years before not only her eyesight but nearly the whole of her eyes, and her reading was accomplished with her fingers, thus showing that nerves below the cranial may under some circumstances attain the same bad privilege.

It is, of course, conceivable that any one of these important conditions, if brought to bear upon a system which is by birth or by education of impaired resistance, should by itself be applicable to all cases of neurasthenia as the sole cause; and it is, of course, equally possible that all should be present in only one case, but the probabilities are immensely against either of these extreme alternatives.

The unquestioning acceptance of any one of these or its overwhelming prominence in the mind of the practitioner tends to relieve him of the responsibility of making the decision as to which is operative in the case before him, but his knowledge of the possible presence of any one or any two or three of them places it upon him rather than upon the specialist. The general practitioner or the neurologist is the center toward which all the lines converge, and although it is more than should be asked of any man in these days that he should be familiar with the details of all the specialties, he should be able to follow the most important clues far enough to decide when to call in his brothers whose knowledge is more restricted and consequently more precise, and whose treatment can be more accurately adapted to each individual patient.

THE INTRA-ABDOMINAL RUPTURE OF OVARIAN CYSTS. WITH REPORT OF A CASE.*

BY ERNEST BOYEN YOUNG, M.D., BOSTON,

Second Assistant Visiting Physician for Diseases of Women, Boston City Hospital; Assistant in Gynecology, Harvard Medical School.

ALTHOUGH intraperitoneal rupture of the smaller ovarian cysts must happen quite frequently, rupture of the larger cysts is more often read of in textbooks than seen in medical or surgical experience; so that the occurrence of such an accident in the Boston City Hospital seems worthy of more than passing mention, especially as there is but one other of its kind to be found in the records.

For many years, and in fact until the third decade of the century just past, the diagnosis between the ovarian cysts and encysted collections of ascitic fluid seems to have been seldom made during life. This is not to be wondered at when we stop to consider that the abdomen was practically unknown to surgery and the only relief for either lay in tapping with the trocar.

Early operation, practiced to-day upon all ovarian tumors, has no doubt materially lessened the chances of such unfortunate accidents, and the instances which appear in the medical journals seem comparatively farther apart as we approach the present time.

In looking over the works of the older writers, the first report of the rupture of an ovarian cyst is that by Fabricius Hildanus [1] (1560–1634), who described the rupture of a dermoid cyst through the abdominal wall.

Wepfer [2] (1620–1695) described what was probably an intra-abdominal rupture, which is cited by Morgagni [3] (1682–1772), who in his turn gives us the history of one in his own experience. In both instances the exact diagnosis was not made.

Mauriceau † (1637–1709) evidently saw a case of this nature, but it is uncertain whether he recognized the condition, considering it apparently, like many of the older writers, an encysted ascites.

Bacher,[4] in 1705, described a rupture and Monro,[5] in 1770, cited the case of Haller (1707–1777).

Camus,[6] in 1844, wrote the first scientific paper on this subject, collecting some cases from literature and adding his own; while Chereau, in 1847, published a few statistics.

Next Tilt,[7] in 1848, collected 71 cases where the tumor discharged into the peritoneum, including 5 ruptures of the tubes, and Palm,[8] in 1868, published 25 cases in connection with his thesis, in all of which rupture was due to stretching or thinning of the cyst wall, or to outside trauma.

Kroker,[9] in 1869, took the etiology of the perforation of ovarian cysts as the subject of his thesis, and Spiegelberg,[10] in 1870, had an article in the *Archiv. fur Gynakologie* on rupture into the peritoneum.

Nepveu,[11] in 1875, was able to gather 128 cases for his article, which is probably the most complete list prior to our more modern surgical methods.

Olshausen's [12] section on "Die Krankheiten der Ovarien," in Billroth's "Handbuch der Frauenkrankheiten," contains a good summary of the information upon this subject, a certain amount of bibliography and references to illustrative cases.

Aaronson,[13] in 1883, worked up an exhaustive list for his thesis, which numbered 181 cases; and in the same year Waite [14] published a very complete study of the rupture of cysts of the ovary.

In the theses of Hue [15] (1883), Poupinel [16] (1886), Remy [17] (1886) and Sebileau [18] (1889) will be found material of interest in this connection.

To the thesis of Lair [19] (1892) I have not had access, but it is highly commended by Duffner,[20] who in 1893 put forth the most elaborate work upon the subject which I have found, containing a very complete bibliography and 221 cases of intraperitoneal rupture.

Storer's [21] article of 1897 is the best in this country and apparently in the English language, although both English and American journals contain many meager reports of such cases, with either very slight references to literature or more often none at all.

The foregoing brief synopsis of the bibliography of this subject will be found to contain the principal articles, and any one who takes the trouble to peruse them will possess a good knowledge of the subject.

CASE. S., female, single, forty-two years of age, was admitted to the gynecological service of the Boston City Hospital on Feb. 24, 1903, having been referred by me from the Out-Patient Department a few days previous.

On entrance she complained of pain in the right lower quadrant of the abdomen and said she thought she could feel a "lump" growing. For three months previous to entrance she had vomited occasionally and suffered from constipation, although formerly quite the reverse had been true and on two occasions, eight and ten years before, she had been treated for diarrhea at the Massachusetts General Hospital. During the last ten years she had been a constant sufferer from indigestion. There had been no menstrual flow since the previous November.

Physical examination. — Well developed, poorly nourished; pulse 104, of fair volume and tension.

* Read at a meeting of the Obstetrical Society of Boston.
† Observ. 289. Quoted by Camus.

mobile, *i. e.*, not attached by cartilage, and this he calls a " stigma neurasthenicum," thus making of the whole an inverse order to that of Glenard.

Some recent observations at the Boston City Hospital by Larrabee with reference to the movable kidney, care being taken to get the patient's account of the symptoms before being informed of the presence of anything abnormal, show by no means an intimate connection between the displacement and general nervous symptoms. Neurasthenia was found in not far from equal frequency among those who had and those who had not the movable kidney. Ptosis of the kidney, alone or with other organs, was considered to be the cause of the symptoms complained of in but 14% of the patients presenting this lesion.

Dyspepsia not associated with enteroptosis, or perhaps it would be safer to say not known to be associated with it, is well known as perhaps an accompaniment, but by many considered a cause. The all-embracing "lithemia" has been assigned a very important share in the production of nervous headache, such as would be considered by many physicians as close upon neurasthenia. Dana, for instance, remarks," A chronic headache not due to tumor or meningitis or syphilis is almost invariably of neurasthenic origin." The paroxysmal or sick headache or migraine is by many given the same etiology.

In a considerable number of quantitative determinations of uric acid in the urine I was unable to trace any correspondence of any form of headache with either excess or diminution of the amount eliminated daily, and it is fair to conclude that if the headache is not due to uric acid the disease of which it is a very common symptom is not of lithemic character, unless the word is used to signify a condition of poisoning by some as yet unknown product of imperfect digestion. Of such a theory we can only remark that, although it seems very plausible, there is as yet no chemical proof to incriminate any special substance.

Anemia is perhaps even less to be considered of importance as a sole cause. Although of course the nervous centers must have their supply of nourishment in order to work, and hence must suffer from a deprivation, yet the mental affection of starvation is a delirium which does not result in permanent nervous breakdown. I have not been able to find a case of permanent or chronic breakdown among the professional fasters and a few others who for some reason have denied themselves food.

The nervous system seems to have the last claim upon such little nourishment as may be circulating and is kept going in as near an approach to the normal form as any other. The inanition of animals experimented on has been found to bear less hardly on the nervous centers than elsewhere.

Certainly no local draft of energy could be more ingeniously adapted to bring out the earlier symptoms of neurasthenia and to develop them to the full in cases of lesser resistance than a pair of eyes incapaole of perfect function separately or together, and yet not so thoroughly unfit as to completely prohibit their use for near vision. The constant and constantly unsuccessful attempt, from which there is no natural relief but disuse, and with necessity or ambition constantly pushing the imperfect organ to its never satisfactorily accomplished function, and then, too, this organ, the one upon which so much of useful activity in the higher walks of life depends, together with the psychic strain under feelings of failure and disappointment, make the ideal combination to develop nervous exhaustion under the highest tension possible. To this pitiable condition all mankind (or all civilized mankind), according to Dr. Gould, approach more or less nearly.

There is not even optically a perfect pair of eyes. " The one pair that had been pronounced mathematically perfect by the most expert testimony I demonstrated had myopic astigmatism, and this defect caused repeated and severe subconjunctival hemorrhages." This statement, which practically agrees with many other authorities, might at first be taken as not very important and merely one of those utterances of the hypercritical to whom nothing that nature makes is quite right, such as the symmetry of the two sides of the body, the arch of the palate, the shape of the ear, the color of the eyes, the position of the uterus, the length of the legs, the activity of the reflexes and so on; but it is really quite a different matter, for Dr. Gould states that " the evil reflexes are the worst in the low defects, — those that the eye can overcome by intense effort, but only for a short time."

He does not claim that all or nearly all of these become neurasthenia, but that a constant strain manifesting itself at first by constantly recurring headaches and by more remote symptoms, among which dyspepsia holds a very prominent place, goes on to neurasthenia only in those cases where resistance is congenitally or by training or by other causes of depression diminished below the point where it can easily be restored by a short rest.

Indeed he denies in the cases of many of the distinguished persons whose cases he has so carefully studied, and who suffered almost exclusively (according to his diagnosis) from eyestrain, that any condition of neurasthenia existed. A proof that a great majority of those who suffer in this way do not go on to a complete development is to be found in the relief, not only complete but immediate, which they experience from getting the properly fitting glasses. They are rather to be regarded as fatigue, extreme indeed and constantly recurring, but restored often enough by daily rest or by a longer abstinence from study to prevent their going on to exhaustion. Dr. Gould's contention, as understood from his various publications on the subject,[1] including the study of the ill health of a number of distinguished literary persons, is that a very large part of the chronic ill health, including dyspepsia, of men and

[1] Biologic Clinics, 2 vols.

women, distinguished and undistinguished, literary, artistic, as well as all handworkers who must use their eyes for near work, is due to eyestrain. That this eyestrain is largely unrecognized, although better known to the laity than to the rank and file of the medical profession and even to many oculists, is owing, firstly, to the fact that the strain does not make itself felt in the eyes, but is reflected to more distant organs and, secondly, to the neglect and indifference not only of general practitioners and other specialists, but of many oculists as well.

This arraignment of his confreres, which he makes to bear especially upon the European oculists, seems a very strange one to affect men brought up in the very birthplace of scientific ophthalmology, but it is really not without its justification in the literature at least, however it may be in practice. It is certainly to be wondered at that such indifference should exist, since the knowledge of the relationship of many cases of headache to defective or painful vision and consequent eyestrain was pointed out very carefully by Weir Mitchell so long ago as 1874, 1875 and 1876, having been hinted at previously by others, as he himself points out.

There has certainly been time enough for such important knowledge to have crossed the ocean and to have become generally known even among those who are not in the habit of looking to this side for valuable suggestions. Of seventy-four persons whose writings are catalogued under "eyestrain" in the supplement volume from the Surgeon-General's library, one only is a German, who wrote a thesis "De copiopia," and one Austrian, who wrote, not of the effect of eyestrain upon the general health, but of the effect of school life on the eyes. Nearly all of the remainder were Americans.

Dr. Gould's explanation of the fact that in many cases the eyes themselves give but little sign of local trouble, but that the symptoms are so distant as to throw not even a suspicion on the organ which has been at the bottom of the whole mischief, unsuspected for years, is an ingenious but hardly adequate one. He says that the eye is such a precious organ that it must be preserved at all costs from any organic disease by throwing the irritation arising from its defective function as far away as possible, and therefore beside the headache, which seems very rarely, until a few years ago, to have made any one think of the eyes, we have nausea, vomiting and all the accompaniments of nervous dyspepsia. It certainly seems as if the good dame would have acted more wisely and more mercifully if she had been a little less careful and allowed a symptom or two to have pointed the way to relief instead of allowing all this mischief to go on unsuspected for so many years. Final causes are double-edged tools in natural history. The decision as to the numerical proportion of cases of defective eyes which cause headaches, which are cured and which get only that relief which comes with the establishment of presbyopia and which go on to neurasthenia can only be made by the oculists or those practitioners who keep closely in touch with them so as to know what happens to their patients after they have been properly corrected.

One who is not a specialist can only take opinions. There are many sets of observations which show a very large percentage of cases of headaches cured or relieved by proper glasses. There are many neurologists who are perfectly aware of the importance of this origin, and it is difficult to understand how any American neurologist, at least, can help being aware of it, even those who do not accept the theory in the wholesale way that it is laid down by Dr. Gould. If the general practitioner should be inclined to criticize the extremest views in the light of the cases he has seen who have come to him for the relief of headaches after they have used glasses prescribed by presumably competent oculists, he would be headed off by Dr. Gould's "Sixty-eight Reasons why Glasses did not give Relief."[2] He finds, indeed, as the first one "that the patient's complaint may not be caused by eyestrain," and that may be just what he was thinking himself; but he cannot get much satisfaction out of it unless he can ascertain that the man who fitted the glasses lived up to a standard of competency and ethics which is very carefully described, but which will be hard to find fulfilled in every particular; that this man should have used the right mydriatic, in the right way, the best trial glasses and the best frames, and has seen that the patient and optician always kept them in order; and that he did not have "some prized fad or method, as retinoscopy, a peculiar drug, a mechanical device, optometers, refracting machines, etc., in the use of which facts must accommodate themselves to the fancy instead of the facts fashioning the diagnosis."

Certainly if these machines, which the non-refractionist looks upon with admiring awe and has been led to suppose have reached the acme of mathematical precision, and to be free from the least taint of the personal equation, do produce such effects upon the mind, even the general practitioner can understand that their use is greatly to be deprecated.

The cases of the several distinguished persons so carefully studied and so graphically described by Dr. Gould are not so conclusive to the non-oculist as they seem to be to him. There is too much which is perfectly clear to him which does not compel the assent of others and which seems susceptible of other explanations, or at least indicates that other factors may have been present and may have been the more important. It is surely within the limits of possibility that dyspepsia may have had other causes than eyestrain and that outdoor life and relief from anxiety might have benefited it even if not due to this one cause. Some of these people may have had enteroptosis, and it is even possible that other reasons which one does not publish in an autobiography may have come into play.

It would, perhaps, be unfair to argue that the

[2] Amer. Med., July 4, 1903, p. 20.

breakdowns in later life — whether of men in active business or of women engaged in the self-imposed tasks which they are pleased to term their social duties (such cases are not alarming), or much more probably and seriously those of a class who figure on the books of institutions as "no occupation," meaning in reality a dozen which do not count because from no one of them can they gain a living — do not necessarily imply any cause outside the life work, but do testify to a wrong method of conducting it, either by choice or by necessity.

Many are, of course, neurasthenia by courtesy only, but many others present the purest type of those forms which begin at the psychic center. Bartholow pithily remarks: "When a man says he is suffering from efforts of mental overwork I want to know what his vices are. Worry may be one of them. It is the ease and luxury of American life that cause mischief. It is the indulgence in eating and drinking, the abuse of alcohol and tobacco, sexual excesses, sedentary habits and too luxurious lives generally, that induce the state of the system called nervous exhaustion. I deny that it is a primary nervous affection and that it is a substantive disease. I hold that it is symptomatic and secondary." These remarks are true and perfectly applicable to the first of the cases which he gives as typical, but it is one which I should not consider true neurasthenia at all. In the second there was a comoination of dyspepsia, malaria and unusual mental exertion.

It is, however, possible for intense intellectual exertion involving an emotional element to be the source of great fatigue without calling in any secondary cause or primary weakness.

James Russell Lowell, who was no weakling, but whose personal feelings were deeply involved in his task, after several days' ineffectual brooding over the "Commemoration Ode," completed it in six hours, two days before it was to be delivered, and afterward wrote that it "made him lean and so nervous that he was weeks in getting over it." This was not neurasthenia and there was no danger of it. It was the natural effect of intense intellectual effort upon a thoroughly sound and healthy nervous system, a system controlled by a genius as far removed as possible from any trace of degeneracy.

But if a lesser man had had his daily bread to earn by a similar task every week and were aware that he was not doing it well, he would need but little outside pressure to bring him dangerously near the line. Then if, according to Stiller, he were pale and lean and his tenth rib were not united by cartilage to the sternum, or if, according to Glenard, his abdominal viscera were not firmly fixed in their places, or if, according to Bartholow and many others, he were to try to indulge in that ease and luxury which are not very likely to come to a man in his position, or if he tried to keep himself up to his work by alcohol and tobacco or cocaine or "nerve tonics" (which might be the same thing), or if, according to the Austrians and French, he appealed to Venus rather than to Bacchus for relief, or if, according to Stevens and Ranney, he could not easily converge his eyes upon his paper, or, according to Gould, could not focus them in their different diameters alike, he would surely cross the line.

If he had done or suffered all or several of these things it would depend upon the physician into whose hands he fell to say which one was responsible and whether he should get good advice, baths, calomel and exercise or have his kidneys triced up or his eye muscles cut or only put on the right pair of spectacles and go off a well man.

The influence of the sexual organs and either the overexercise or suppression of their normal function upon the development of neurasthenia has been from an early day in the distinction of this as a separate condition, and indeed, in a more general way, almost from the beginnings of medicine, invoked as a powerful one.

There can, of course, be no doubt of the deep and far-reaching associations of this primitive and powerful impulse with all parts of the system, physical and psychical, but of the actual effect of organic disease, or much more of misuse and irregularities of function, in the causation of neurasthenia and allied conditions it is difficult to speak statistically without inquiries more minute and embracing larger numbers than would be easy in the face of American and English reticence upon such matters, but it is not going too far to say such a causation would be found a real one, or at least the preponderating element, in many more cases than would appear upon the records. As a sole determining cause, however, and as covering the great majority of cases, I have little doubt its frequency has been exaggerated.

The theory of ovarian irritation as a cause not only of local pains, but of general nervous breakdown, leading to so-called "normal" oöphorectomy, has apparently passed through that boom period with which each novelty in treatment is favored among us, and at present finds its application, as its proposer, Battey, expressly said it should do, only in the extremest cases where there is practically no other hope of relief.

The question of the influence of pelvic disease, and the same might be said of the other kinds of local irritation, can only be fairly looked at in tne opposing light of the well-known effect which nervous and general debility has in aggravating the severity of any local lesion upon the system. The patient labeled neurasthenic may be immensely benefited by local treatment, but, on the other hand, many a woman has gone through with this in good hands without relief until she has had a thorough rest and treatment directed to her general condition. In the given case it is likely to happen that neither the gynecologist nor the neurologist can establish a clear and exclusive claim and the patient benefits by their co-operation.

The phrase "sexual neurasthenia" is applied to cases in which real or supposed sexual abuses or excesses have been more or less important factors in the origin and in which the symptoms are especially connected with weakness of the sexual

function. In many cases of this kind the condition is the product of more than one factor.

The symptoms as regards their intensity and tenacity are determined by the loss of energy in many directions, of which the sexual is only one, but the emphasis of the hypochondriacal disposition is likely to be determined chiefly by that which takes so strong a hold on the imagination, and is felt in the corresponding centers. Every practitioner is aware how easily the thoughts and attention and apprehensions of a young man can be turned in this direction by the slightest departure from the normal, aggravated by timidity, self-reproach and quack literature. The actual influence of this set of causes it is impossible, as remarked before, to express in percentages, but is undoubtedly very considerable.

Some recent foreign observers and theorists have made the connection between this class of causes and certain groups of symptoms a very exact and definite one, assigning not merely sexual excesses and abuses as one among several causes of functional nervous diseases, but each special form to a special set of symptoms. Neurasthenia proper is thus referred almost exclusively to solitary sexual indulgence, while Freud and his followers, whose psychical analyses, both in this and other departments, are certainly very ingenious, claim that the " phobias," or morbid fears of various kinds, which he separates off as a distinct group from neurasthenia, but does not unite with any form of insanity, owe their origin almost as exclusively to incomplete sexual relations or to enforced continence under temptation.

Many years ago Beard mentioned rather casually that in a few cases he had noticed a connection of this special kind.

These views, although highly important and interesting, are by no means universally accepted even in Europe, although several inquirers have gone over the ground carefully with confirmatory results.

Whether the much greater richness of Continental literature on these subjects has anything to do with the relative frequency of these vices and abnormalities in the Latin and Teutonic peoples would be a very interesting question if facts were obtainable to answer it.

These "phobias" "névrose d'angoisse," a general condition of timidity and fear developing into special and definite forms, sometimes approaching the distinctly insane delusion of persecution or *folie du doute*, are separated off from neurasthenia into a group by themselves as wanting in its most characteristic symptoms and as having this peculair and different etiology.

The coincidence of neurasthenia and sexual abnormality of any kind cannot be considered proof that the former is the result of the latter without further inquiry. The causation may be in the other direction. Abnormalities of all kinds are well-known accompaniments and symptoms in many neuropathic conditions as well as in actual insanity.

Symptoms of difficult and imperfect digestion are among the most frequent among what may be called the secondary ones of neurasthenia, that is, not secondary in point of importance, not much so in point of time, but simply as being less closely connected with the essential disorder. They aggravate it and are caused by it and, by supplying a new source of irritation and by interfering in the nutrition of the nervous centers, establish a vicious circle of a very obstinate kind. There are, however, theories of dyspepsia, using this term to cover the whole group, which make it the essential and important condition, either of neurasthenia itself, or of the earlier symptoms which point in that direction, and, upon the addition of some other irritant, run into it. Glenard sees but little distinction between the aggravated dyspepsia dependent upon enteroptosis and what he calls neurasthenia as he defines it in the paragraph already quoted. The influence of floating kidney or nephroptosis was long ago suggested as one cause of dyspepsia upon purely mechanical grounds from a pulling of the pedicle around the duodenum.

Important and accurate as Glenard's observations were as applied to the patients upon whose cases he based his work, yet looking at his definition and admitting that it does correspond to a good many of the diagnoses made, it is evident that his cases at Vichy were of a special class and selected not by himself indeed, but probably largely by fashion and tradition, and that a bath-physician is likely to see chiefly one special division of the class.

Others who recognize Glenard's correctness in associating dyspepsia with enteroptosis take almost exactly the opposite ground as regards the relation of causation with the nervous condition. Thus Stiller thinks that " if we divide nervous dyspepsia [a term which Glenard gives as one of the synonyms of neurasthenia] into three, the first or idiopathic is very rare even if there really is such a thing; the second or reflex has a real clinical significance, as when the stomach nerves are affected from the genital organs, but by far the greater number of cases are of that form which rests on a general neurosis, as neurasthenia where the dyspepsia is only a part of the more comprehensive functional disease." " This most common form is almost always accompanied by enteroptosis of greater or lesser grade; it represents the real congenital enteroptotic dyspepsia, so far congenital as that the splanchnoptosis as well as the dyspepsia develops itself in youth on the basis of congenital neurasthenia and the atonic bodily condition which belongs to it." He thinks that the type of case described by Glenard has been long recognized, not on the basis of a minute abdominal mapping out of location, but of the general appearance, " the pale, lean, delicately built young men and women, with dyspeptic and nervous complaints or even nervous expression of face, thin, soft belly, a flaccid, splashing stomach and the right, or both, kidneys movable."

One of the most interesting points of this paper is that in a large number of pale, lean, nervous dyspeptics he finds the tenth rib usually

Heart and lungs negative. Abdomen distended by a hard symmetrical tumor rising from the pelvis and extending to the umbilicus. Fluctuation wave present. Dulness over the tumor and in the right flank; tympany above the tumor and in the left flank. No alteration of percussion note with change of position. No edema; apparently no ascites; urine negative.

Owing to the rather poor condition of the patient it was considered best to wait for a few days and attempt to build up her general health. During her stay in the ward the temperature was slightly elevated, while the pulse kept falling, although there was at times some complaint of pain in the right lower abdomen. On March 1, in the early afternoon, vomiting commenced, and at the same time she suffered from abdominal pain. About 6 P.M. there came a marked deterioration in the pulse and the patient suddenly collapsed, the pulse being imperceptible at the wrist. At this time she complained of general abdominal discomfort, but no localized pain. A little later I saw her in consultation with Dr. George Haven, and at that time there were signs of free fluid in the general cavity and a diminution in the size of the cyst. The condition of the patient made operation at the time inadvisable; but although freely stimulated and given subcutaneous injections of salt solution, she failed to react and died about half-past five the next morning.

PARTIAL REPORT OF AUTOPSY BY DR. E. E. SOUTHARD.

Autopsy eighteen and three-quarters hours post-mortem. Slender white woman with delicate musculature and nutrition slightly lowered; body still warm; traces of lividity; breasts ill-developed; abdomen prominent.

Peritoneal cavity. — Upon incision a great quantity of yellowish fluid containing leucocytes, possibly three liters (two liters caught in graduate and measured) flows out, at first under some tension. The omentum is glued both to anterior wall of abdomen and to coils of bowel by tolerably firm, fibrous adhesions, as well as by fibrinous bands and bears upon both surfaces a considerable quantity of pus containing many leucocytes. (Organisms not demonstrated in smear.) Upon laying back the omentum the bowel is exposed, containing only a moderate amount of gas; there is minute injection, especially at the apposed edges which are sticky and covered with a thin, slightly greenish layer of fibrin; the fluid in the iliac fossæ and in the lesser peritoneal cavity is a little thick with fibrin; the lower third of the abdomen is filled with a multilobate tumor mass, to which the appendix, cecum, some folds of the small intestine and focal areas of the parietal serosa are united by adhesions. Upon lifting out the purulent fluid from the pelvis the rather small uterus is exposed, veered somewhat posteriorly and superiorly by the firm attachment of the right tube to the tumor mass. The various adhesions of the tumor mass are rather easily separable. Upon removal the mass weighs 570 gm. Its various lobes range in diameter from 1 to 4 cm. and are variously colored from clear porcelain white to diffuse pink; many of the folds and loci of adhesions show minute arborescent injection. The mass as a whole is fairly firm; many of the lobules are elastic and contain purulent fluid under tension. The smaller excrescences and some of the larger lobules are solid, but nowhere so firm as the normal ovary. One of the cysts presents a round aperture 5 cm. in diameter, which at autopsy goes upon and is adherent to a reddened fold of the ileum. Upon separation of the fold of ileum a great quantity of purulent fluid can be expressed from the cystic cavity within. The mesenteric lymph nodes of normal size and appearance. Diaphragm fifth rib left; sixth rib right.

Pleural cavity. — Normal.

Pericardial cavity. — Visceral serosa shows whitish thickening along anterior coronary.

Heart. — Weight 210 gms.

Measurements: Tricuspid valve, 11 cm.; pulmonary valve, 8 cm.; mitral valve, 6.5 cm.; aortic valve, 7 cm.; left ventricle, 1.5 cm.; right ventricle, .3 cm.

Spleen. — Weight 75 gms. Capsule bluish gray, lax, covered with fibrin; substance soft, reddish gray; slightly pulpy.

Gastro-intestinal tract. — Not notable.

Pancreas. — Not notable.

Liver. — Weight 1,140 gms. Brownish gray; somewhat soft and takes the thumb nail readily; lobules scarcely evident; lobule centers a little red.

Gall bladder. — Normal.

Ureters. — Normal.

Left ovary, uterus and tubes. — Normal.

Uterus contains glairy mucus. Right ovary replaced by tumor above described. Tumor on section consists of an association of geode-like masses with thick injected walls whose papillary structure can sometimes be made out; the fibrous columns which run out from the capsule are surrounded by grumous white material which may be teased into multitudes of gray knobs and threads. The cavities are occupied with cell detritus and leucocytes, in which no organisms are demonstrated in smear.

Anatomical diagnosis. — Epidermoid carcinoma, infection of lobules of tumor, rupture in the peritoneal cavity with acute fibro-purulent peritonitis, chronic adhesive peritonitis, sclerosis of mitral valve.

The autopsy showed in addition general arteriosclerosis, but nothing especially important concerning our subject.

Etiology. — Unfortunately it is impossible to ascertain the exact cause of rupture in many instances, as when recovery takes place this matter must very often remain unsettled and even after autopsy the reason is not always clear.

Duffner found a cause mentioned in only 38% of his 221 cases, while Storer in 108 was able to assign a cause for only 30% and "in many of these the assigned cause was at least questionable." In 46 cases which I have found in literature since 1893, a cause is given in only 16, and among the whole number were no autopsies of any worth, and 3 reports of the condition of the abdomen at the time of operation, which render it possible to make a diagnosis as to the malignancy of the tumor.

Cysts of the ovaries are formed at all periods of life from infancy to old age, and consequently the frequency of rupture at any given period corresponds to their prevalence at that time. According to the figures of Duffner, the decades from twenty to fifty years seem to present about the same number, while from fifty to sixty years the proportion is diminished. Before twenty and after sixty years the number is notably decreased. Jenkins [22] reported one in a child of between three and four months; while somewhere, the reference to which I am unable to give, I have seen an account of a rupture at seventy-nine years. The size of the tumor seems to have little significance, except that increased bulk must make it more liable to trauma. It suffices to say that all sizes have ruptured, that the attendant results have often been as widespread with the small

as with the greater, and that apparently multilocular cysts rupture most often, owing, no doubt, to the many degenerative changes to which they are subject as well as their greater liability to external violence. The escape of cyst contents into the abdominal cavity is generally spoken of as "rupture," a name which it seems best to accept, but on inquiring into the etiology of these unfortunate events we find that the appellation is not strictly correct for all.

Rupture implies a sudden solution of continuity, while we know that certain of the changes which allow of the discharge are of gradual origin and partake of the nature of a perforation, although the final escape may be hastened by violence of muscular action or external traumatism. This difference is perhaps rather fine for clinical use, but it is just as well to recognize the distinction.

Broadly speaking, the factors concerned may be classed under three great headings:

I. — Predisposing causes.
II. — Alterations in the cyst walls.
III. — Trauma.
(*a*) External.
(*b*) Internal.

Naturally various combinations of the above may contribute to the collapse of these new growths.

Predisposing causes. — It is now generally recognized that the difference between unilocular and multilocular cysts is one of degree and not of kind, for in the walls of those clinically monolocular we find small cysts or upon their walls the remains of partitions which have disappeared, showing that the monolocular cysts were once multilocular. The nature of the cyst walls and their contents have clinically an important bearing, for multilocular and parovarian cysts with thin or friable walls are more liable to rupture than the thick, monolocular or dermoid cysts, and again those with viscid, jelly-like contents burst more often than those with the thin, serous contents. Rapid rise of internal pressure may affect the integrity of the wall, as it becomes unable to accommodate itself to the increased strain. Formerly this was said to be brought about by increased secretion, although the more modern view is that cells cannot secrete under extreme pressure.

In addition, we find as causes of increased pressure, rapid growth of large papillary vegetations and hemorrhage into the cavity, while torsion of the pedicle by inducing a passive congestion tends toward the same end. Thornton [23] reports 9 ruptures among 57 cases of torsion. Adhesions, when numerous and firm, hold the tumor in one position and prevent its escaping violence by slipping to one side or accommodating itself more or less to the varying movements of the body. Even a single strong adhesion may be as dangerous as many, for a strain brought upon it by a sudden movement of the cyst may end in tearing the walls.

Changes in the cyst walls. — These play an important part in the rupture of the larger cysts, especially the papillary cystomata. Here the growth often invades the wall, weakens and finally destroys it, producing what was referred to above as a "perforation." Interference with the circulation by thrombosis, as described by Sir Spencer Wells and Mayne,[24] may end in fatty degeneration, calcareous deposits and gangrene with perforation.‡ Hemorrhage into the cyst walls may lead to the same result. Infections easily pave the way for rupture, but this happens proportionately less often as the inflammatory disturbances cause adhesion between the tumor and surrounding structures. But in spite of the safeguards by which nature attempts to prevent fatality, the wall, softened by the inflammatory processes, becomes unable to withstand the internal pressure and gives way before adhesions have made a general peritoneal infection impossible. As dermoids are most liable to these changes, we naturally find them predominating in this class if we exclude other cysts infected by aspiration. Lair [25] considers that the healed scars of old ruptures are weak points, as they contain few if any vessels and are endowed with poor vitality. For this reason they may be the common cause of repeated rupture. Torsion of the pedicle, mentioned above in another connection, may induce changes by shutting off the blood supply, or rendering the wall more frail as it becomes softened by the edema. Finally, perforations may be simple or multiple. Spiegelberg mentions one with thirty openings from the size of the palm of the hand to that of a pea.

Trauma. — Under this heading come many peculiar accidents: Falls on the head, missteps, blows, kicks, jolting of vehicles, straining at stool, vomiting, sneezing, coughing, coitus, compression by bending forward and lastly those which have ruptured under examination, obstetric operations or as the result of tapping with trocars. Pregnancy and parturition seem responsible for a certain number of traumatic cases, either from pressure upon the tumor by the gravid uterus, by torsion of the pedicle or by muscular effort during labor.

Storer in his series found 70 cases of traumatic rupture: Falls, 34 (12 stated to be upon the abdomen); external violence, 36 (kicks, blows, etc.). Tapping, 1; version, 2; examination, 10; forceps, 3; coitus, 1; masturbation, 1,— the rest from various causes.

In quite numerous instances cysts have disappeared under the examining hand, twice in the city of Boston (Chadwick,[26] Storer), and in tapping, the pressure upon the abdomen has been sufficient to rupture a thin or diseased wall.

Symptoms. — In connection with impending rupture certain symptoms of an uncertain nature are present in many instances. Chief among these is pain, extending often over many months and of varying intensity, which according to Hue, Huges Bennet considers due to ulcerations of the walls. Another quite common symptom is rapid increase in the size of the cyst. Both of

‡ See Meredith: Trans. Path. Soc. of Lond., Dec. 16, 1869.

these seem to be present in a sufficient number of cases to warrant being on our guard when they appear in a patient known to have an ovarian tumor.

Nearly all writers agree upon the general symptoms of intra-abdominal rupture at the time of its occurrence, although in a given instance any or all symptoms may be absent. Hofmeier,[27] on the other hand, says that subjective symptoms are rarely present, and Schroeder [28] remarks that rupture of the cystic pockets is of daily occurrence, and generally unperceived. In spite of the opinion of the two previous observers, the cases which we see clinically generally present a certain number of a definite train of symptoms:

(1) A feeling of something giving away and the outpouring of fluid into the abdomen.

(2) Pain: Severe, mild or none at all, but usually considerable with the larger cysts. The character of the fluid seems to have little connection with the causation of pain except in the case of purulent collections and in certain cystomata with gelatinous contents.

(3) Tenderness of the abdomen.

(4) Collapse: Either from intense pain, hemorrhage or what is apparently an irritation of the peritoneum, due to the sudden influx of fluid or to an irritant quality in the fluid itself.

(5) Nausea and vomiting: Probably a sympathetic phenomenon from peritoneal irritation. Palm found it to be present in 4 out of 25 cases.

(6) Fever: Present in most cases after a certain time (Palm).

(7) Disappearance of tumor and change in form of abdomen.

(8) Free fluid in the abdomen, if the quantity is large enough to give signs of physical examination.

(9) Palpation of the remains of the tumor. This is often possible, especially in multilocular cysts, as usually some part remains intact.

(10) Increased urinary excretion. Disse's [29] case passed 25 liters in two days and in some this has been the only symptom, recurring with each rupture.

(11) Tendency to sweat (Simpson [30]).

(12) Loss of friction of tumor upon abdominal wall.

(13) Presence of peptones in the urine. For further consideration of this subject the reader is referred to the theses of Wassermann [31] and Isaackides.[32]

Prognosis. — The mortality of the older writers was based upon non-interference; so that their figures are not suited to the present state of surgery, but they do give us an insight into what happened with no surgical interference.

Looking over the literature for the past twenty-five years, it is amazing how many articles have no reports as to malignancy, the cysts being classed as monolocular, multilocular, etc. Another drawback is the fact that the subsequent history of those who did not die within a short time is wanting, and undoubtedly if we could know this we should find many reported as cured dying later of malignant disease. We are also justified in believing that many more recoveries (both spontaneous and after operation) are reported than the less fortunate results, which are perhaps, in the long run, quite as useful to the clinician as those of favorable outcome with no pathological report. It is for these reasons that the present case has been reported.

The immediate results of rupture are very variable. Small cysts, as we have previously said, often rupture without symptoms and there are numerous instances in which the repeated rupture of larger cysts has had no deleterious effect upon the health of the individual and has eventually brought about an apparently lasting cure. However, for the complete recovery of the patient three essential factors are necessary: First, that the cyst be unilocular; second, benign; third, that its cavity become obliterated. This last may be brought about by retraction and shrinking of its walls, or by the effects of peritonitis (Olshausen). Continued contact may produce agglutination of the cyst walls and ultimately end in its obliteration (Simpson). Olshausen says that the contents of the anatomically unilocular cysts are innocuous whether they spring from the Graafian follicles or from the Wolffian ducts. Spiegelberg and Olshausen also consider the fluid of the colloid tumors, when not contaminated by blood or pus, as generally harmless, but not so readily absorbed by the peritoneum. Still this cannot be considered an absolute rule, as Olshausen cites a case of his own where there were marked signs of peritonitis at the time of operation. The size of the cyst may have a bearing, as the sudden gush of a large quantity of fluid into the peritoneum, even if quite unirritating, may produce shock, and the emptying of the contents of a small cyst has caused fatal peritonitis. Chrobak [33] reports a death from the bursting of one the size of a hazelnut. Nearly all writers agree that the most favorable outlook is in ruptures of the parovarian cysts; but indeed these are not without danger, as Goodell [34] has seen two terminate fatally. The unilocular ovarian cysts are also accorded a favorable prognosis by some, while others like Matthew Duncan, quoted by Tait,[35] reserve spontaneous recovery for the parovarian alone. Certain tumors after numerous ruptures seem to give no further trouble. Palm reports two and Aaronson seven such cases; but it seems probable that in most of these the rent was so large as to give constant drainage to the cavity, the fluid being absorbed by the peritoneum.

It is needless to say that recovery from the papillary cystomata practically never takes place, and unfortunately the rupture of dermoid cysts is almost invariably fatal. Certain individuals survive repeated ruptures, although others recover from some only to die from the results of later ones. Palm reports six deaths after the first rupture and one each after the second and fourth. This difference in the results of rupture in the same case may be explained in several ways: Possibly the first rupture from traumatism and the second from twisted pedicle, in which the prognosis

would naturally be much more grave (Duffner). Hüss [36] considers that different pockets may contain fluids of different character, while Duffner advances the theory that in the interval between two ruptures the contents may change their character. In certain instances, following the gush of fluid into the peritoneum, death takes place from shock before peritonitis has time to develop (see Hue), and in much the same category belong the sudden deaths from the rupture of hemorrhagic cysts (Scanzoni [37]). Storer's case throws some light on the reason for lack of hemorrhage in some instances and the cause of it in others; for the blood vessels with their surrounding connective tissue form the strongest part of the walls, and rupture naturally takes place at the points of least resistance. If, however, as in Storer's case, the tear runs toward the main vessel through the junction of two trunks it is easy to see how laceration of the vessels could occur, while starting in the opposite direction it would probably leave the vessels intact. In the papillomatous cysts decrease of pressure upon the walls may lead to hemorrhage from the veins of the intracystic growths as a result of the loss of support (Greig Smith [38]), and as in the case of Wertheim,[39] may persist for days after the original injury. The duration of life after the accident is very variable, as will be readily seen from what has preceded.

The 22 cases of Nepveu which succumbed were classified: Sudden deaths, 6; death after three to ten days, 10; death after twelve to fifty-five hours, 6.

Duffner found the following length of life in 16 fatal cases: Eleven months, 1; two to fourteen days, 10; seven to twenty-nine hours, 5.

Peaslee has seen 5 cases of rupture of multilocular cysts, 4 of which died within five days.

Storer in an average of the mortal statistics of five writers, containing traumatic and spontaneous ruptures, found a mortality of 41%. In his own series, of which about half were said to be unilocular, 26.8% recovered after varying grades of peritonitis, 44% recovered without peritonitis, and of these 90% were unilocular and "possibly many parovarian."

Aaronson, in 130 intraperitoneal ruptures without operation: Full recovery, 42; death after acute or subacute course, 55; healing after repeated rupture, 7; death after repeated rupture, 14; unknown results, 12.

He also reports 5 ruptures of dermoid cysts with fatal results, and among 121 infected ovarian cysts found 5 intraperitoneal ruptures — all fatal.

The mortality of rupture in the various stages of pregnancy is given by Remy.

During the whole periods of pregnancy and the puerperium 52 ruptures took place in 49 women with the following results: Recoveries, 23; deaths, 24; results unknown, 2. During pregnancy — 19 women with 21 ruptures: Recoveries, 10; deaths, 8; result unknown, 1. During labor — 15 women with 16 ruptures: Recoveries, 7; deaths, 8; During the puerperium — 12 women with 12 ruptures: Recoveries, 4; deaths, 7; result unknown, 1.

The figures of Duffner, based on a series of 31 cases, are much less favorable, as 77% of all cases ended fatally. During pregnancy — total 9: Recoveries, 3; deaths, 6. During labor — total 14: Recoveries, 3; deaths, 11. During puerperium — total 8: Recovery, 1; deaths, 7.

We see that the results in pregnancy grow steadily worse from beginning to close. The trauma and changes in the relations of the pelvic structures which occur during the period of pregnancy, labor and the puerperium, together with the increased facility for infection at such times, render the outlook exceedingly grave.

Treatment. — With the surgeon called to assume the responsibility of such a case lies the question of operation, and though decision is often simple, yet after the rupture of a small cyst with indefinite symptoms it may become a very delicate matter to decide. Unfortunately the size of the cyst gives us no special clue as to its nature, for small cysts, as well as large, have often been the cause of fatal peritonitis. If there is a history of previous ruptures with no untoward results, I think we may reasonably expect a favorable outcome and unless under most favorable surroundings would be justified in waiting. If, however, hemorrhage is taking place or the cyst is supposed to be a dermoid or papillomatous, operation should not be delayed. The dangers of operation in the first two are certainly no greater than those of expectant treatment; and in the last, while the patient may recover for the time being, there is the constant menace of a general invasion of the peritoneum by the cells of the cyst fluid. Indeed monolocular cysts, even with the large number of temporary and apparent final recoveries, seem to me to merit the same treatment if of any size or seen within a few hours after rupture, for their nature is necessarily uncertain and broadly speaking I should consider operation indicated in every case where the surroundings permit.

Spencer Wells had one death in 12 which ruptured before operation, and Knowsley Thornton [40] 3 in 40 cases. Aaronson among 25 operative cases in his series had 4 deaths and 14 recoveries, and Duffner among 70 operative cases figured a mortality of 21%, though many of the deaths were due, as he says, to the enfeebled condition of the patients and to generalization of the growth in the peritoneum.

Soller [41] has proposed paracentesis and, in event of benign fluid, expectant treatment. This proceeding is open to the objection that it is quite as dangerous as an exploratory incision and much less satisfactory. Cysts have been removed during pregnancy without producing miscarriage, but in numerous operations of this nature which it has been my fortune to see, miscarriage has never been avoided. However, considering the high mortality (77%) it hardly seems worth while to take this fact into consideration. If near the end of term and the woman shows signs of labor, Duffner has proposed Cesarean

section and at the same time ablation of the cyst.

As to the question of drainage, there is the usual difference of opinion, Spencer Wells, Hue, Sebileau and Lair favoring its employment in certain cases, while Schroeder, Terrillon and Gross among others consider it unnecessary. Generally speaking, drainage may be said to be indicated in cases with active peritonitis, when the fluid is mixed with blood or is purulent in character and after the rupture of dermoids. Even in some of these there may seem to be no need to resort to its use. When the entire cyst cannot be removed a gauze drain may be used with the hope that peritonitis will eventually destroy the secreting surface. The most important thing is so remove the cyst contents.

In closing I think we may say that the general concensus of opinion is in favor of an early operative treatment and surely the statistics of mortality will bear out such a decision.

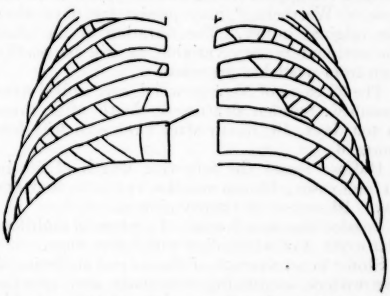
Clinical Department.

A CASE OF TRAUMATIC HEMOPERICARDIUM.



BY JOHN LOVETT MORSE, A.M., M.D., BOSTON,

Instructor in Pediatrics, Harvard Medical School; Assistant Physician at the Children's Hospital and at the Infants' Hospital, Boston.

ANTONINA P., two and one-half years old, was referred to me by Dr. Galbenewetz, July 10. She had always been well and strong. A month before, while looking out of the window, she had fallen forward on a needle which was on the window-sill. The needle entered the chest near the right edge of the sternum and broke off. The mother thought about half the needle remained inside. She was immediately taken to the Relief Station, where a small incision was made over the point of entrance. Nothing was found. The incision healed in a few days.

She was apparently perfectly well for nearly two weeks after the accident. She then began to appear sick and gradually grew worse. Her symptoms were rather indefinite, however. Her appetite was poor, but she did not vomit. Her bowels moved regularly. She had no cough. She frequently put her hand to her side and said that it hurt. She had ceased to run and play but still walked about a little. She breathed hard almost constantly, the respiration often being grunting in character. She slept very poorly but was able to lie down.

Physical examination. — She was well developed and nourished but rather pale. There was very slight cyanosis of the lips and cheeks. When not disturbed her breathing was fairly quiet, but when she was at all excited or moved about, respiration became difficult and was accompanied by grunting. She was not able to lie flat, but was comfortable when reclining. The alæ nasi moved at times. There was slight retrac-

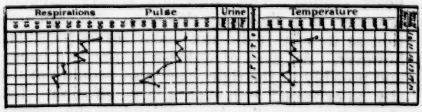
tion of the lower chest with inspiration, but none elsewhere. The throat was normal. The tongue was fairly clean. The cervical lymph nodes were somewhat enlarged.

The thorax was symmetrical. There was no bulging of the intercostal spaces and none of the præcordia. There was no visible or palpable cardiac impulse. The heart sounds were everywhere diminished. They were heard most distinctly just inside of and below the left nipple, but were also heard feebly over the whole normal cardiac area as well as outside of this area, especially to the left. The sounds were no louder when the child was held face downward. The right border of cardiac dulness was at the right parasternal line, being the same in the third, fourth and fifth right spaces. The upper border was at the junction of the manubrium and sternum. There was dulness, continuous with the cardiac dulness, in the first left space and possibly a little higher. This dulness extended over the whole left front and axilla to the posterior axillary line. There was also dulness in the upper part of Traube's space. The character of the heart sounds was normal and no murmurs were heard. The second pulmonic sound was not proportionally louder than is normal at that age. There was a scar of an incision about one-half inch long at the junction of the sternum and the third right space.

Percussion of the right chest showed nothing abnormal except that the upper border of the liver dulness was in the sixth space. The respiration was normal in character but slightly exaggerated. There was slight tympany in the middle left back; otherwise the resonance was normal. There was no area of dulness in either the right or left back. Respiration was a good deal diminished in the left front and axilla but not changed in character. In the back the respiration was slightly diminished but not changed in character. The vocal resonance and fremitus were not obtained. No rales were heard.

The abdomen was somewhat distended but not tense. There were no evidences of fluid and there was no spasm. The upper border of the liver dulness was in the sixth space. The lower border could not be definitely made out, but there was resistance extending nearly to the umbilicus. There was tenderness on the right side from the costal border nearly to the umbilicus. The area of splenic dulness was not determined. The spleen was not palpable. The extremities showed nothing abnormal. The temperature was 100.6° F., the pulse 130, the respiration 50.

Fluoroscopic examination on July 11 showed the cardiac area of darkness beginning on both sides at the first rib, and extending 2½ cm. to the right and 3 cm. to the left of the median line. On the right side the border ran diagonally downward and outward just inside the right nipple to the junction with the liver



shadow in the sixth space 5½ cm. to the right of the median line. The cardio-hepatic angle was obtuse. On the left the line of darkness ran diagonally downward and outward just outside the left of the nipple and joined the abdominal shadow in the sixth space, 8½ cm. to the left of the median line. The border was less distinct on the left than on the right, but clear lung could be seen on both sides. The cardiac shadow did not change with position, being the same whether the child was lying or sitting. No needle was seen. A dark area, continuous with the liver shadow and probably caused by the liver, extended downward to just above the umbilicus and on the right nearly to the anterior superior spine.

While the physical examination pointed strongly to fluid in the pericardium, the signs were not as characteristic as were those given by the fluoroscopic examination. These were absolutely characteristic of effusion in the pericardium.

A needle was introduced into the fifth right space just at the edge of the sternum. A bloody fluid came out under considerable pressure. As a serous or purulent fluid had been expected, it was thought for the moment that the heart had been tapped. The needle was therefore immediately withdrawn. It soon became evident, however, that the heart had not been wounded, as its action continued regular and there were no signs of collapse. The needle was then introduced again into the sixth left space, 9½ cm. to the left of the median line. Dark, bloody fluid came out under great pressure. A little more than 100 cc. escaped without aspiration; 400 cc. more were then withdrawn by aspiration. Cultures from this fluid remained sterile. The general condition was not at all affected by the operation. The heart sounds became much louder and a friction rub appeared over the lower portion of the pericardium. The child was much relieved by the operation and seemed very much more comfortable. She was able to sleep lying down and take her food well.

Examination on the 13th showed a feeble impulse, visible and palpable in the fifth space. The upper border of cardiac dulness was at the upper border of the third rib, the right border 2½ cm. to the right of the median line in the third and fourth spaces and 2 cm. to the right in the sixth space. The cardio-hepatic angle was acute. The left border of cardiac dulness extended 7½ cm. to the left of the median line in the sixth space, and in the fourth space about 2 cm. outside the nipple line. The left front was still slightly dull. There was no dulness in Traube's space. The heart sounds were loud and normal in character. The pericardial friction rub had disappeared. Air entered both lungs equally. The upper border of liver dulness was still in the sixth space. The lower border was palpable about 4 cm. below the costal border, extending a little more than half way from the costal border to the umbilicus.

Fluoroscopic examination the next day showed the upper border of the cardiac shadow at the lower border of the second rib and the right border about 1½ cm. to the right of the median line in the fourth and fifth

spaces. The cardiac apex was under the sixth rib, 6½ cm. to the left of the median line and ½ cm. to the left of the left nipple. The left side was not quite as clear as the right. The diaphragm in expiration was at the sixth rib on both sides.

The cardiac area shown by the fluoroscope was therefore within normal limits. That given by physical examination was larger than normal. It is difficult to explain this discrepancy, but of course the area shown by the fluoroscope must be accepted rather than that obtained by percussion.

The child's general condition improved very rapidly. She was up and running about on July 14 and was discharged well July 15. The temperature was normal after the 10th. The pulse and respiration continued rapid for two days, then became much slower. Just before the child left the hospital radiographs of the chest were taken which showed that half the needle still remained in the body. The needle evidently entered the body just at the right edge of the sternum in the third space, going diagonally upward behind the sternum, the greater part of the needle being behind the sternum, only the end protruding. Operation was advised but refused.

This case presents many points of interest, among which may be mentioned the unusual cause, the peculiar onset, the comparatively slight degree of the symptoms, the absence of many of the characteristic signs of pericardial effusion and the situation in which tapping was done.

The hemorrhage must, of course, have been due to a lesion of the pericardium caused by the needle. In such a case the symptoms would naturally be expected to come on immediately. The fact that they did not can only be explained on the supposition that the needle did not at first reach the pericardium, but later worked its way to it. It would be expected, moreover, that if the needle scratched the pericardium at one time it would continue to do so and that bleeding would recur after the removal of the fluid. That it did not can best be explained on the supposition that the needle had in the meantime become encapsulated. It would seem possible, however, that the needle might in the future cause a recurrence of the hemorrhage.

It is rather difficult to explain the comparative mildness of the symptoms with such a large effusion. The most plausible explanation seems to be that the greater part of the pressure of the fluid was exerted on the liver and diaphragm, pressing them down, and thus relieving to a certain extent the pressure on the lungs and heart. This explanation seems justified by the position of the liver and diaphragm as shown by the fluoroscopic examination.

When there is a pericardial effusion change of position causes, as a rule, a change in the area of dulness; as a rule, too, bending forward restores or increases the strength of the impulse of the heart sounds. This does not always happen, however, as is shown by this case. No explanation as to why it did not occur seems possible, however. An area of dulness in the left back, and possibly in the right back also, would naturally be expected with such a large effusion. Its absence may possibly be explained on the supposition that the fluid all gravitated downward rather than backward.

While the practicability of tapping the pericardium in the fifth right space close to the sternum has been demonstrated experimentally by Dr. Rotch and a number of other observers, the operation has seldom, if ever, been successfully performed during life. The results in this case show that the pericardium can be safely and successfully reached in this situation. The fluid came out under great pressure, and there is every reason to suppose that it could have been withdrawn as successfully here as it was when the needle was introduced into the sixth left space.

Medical Progress.

REPORT ON OBSTETRICS.

BY FRANK A. HIGGINS, M.D., BOSTON.

PUERPERAL INFECTION.

IN a valuable paper on Obstetrical Therapeutics, [1] Dr. C. M. Green again emphasizes the fact that the treatment of puerperal infection primarily rests with intelligent, painstaking prophylaxis, and that the most effective therapeusis against infection is prevention. He says that in teaching the lesson of obstetrical asepsis, too much emphasis cannot be given to the fact that obstetrics is specialized surgery, that there is no essential difference between surgical and obstetrical asepsis; that in obstetrics as well as in surgery, not alone hands and instruments, but the field of operation, must receive adequate antiseptic preparation. The perfect sterilization of instruments is now possible, reasonable care may give suitable preparation to the vulva and to the contiguous parts which need be touched, but the asepsis of the naked hand is still a matter of uncertainty. The use of the sterilized rubber glove removes all uncertainty in this particular, and the time has come when this addition to our aseptic preparation must be accepted and adopted. He has made careful trial of the sterile glove in all phases of obstetric work from simple examinations to difficult operations, and he is fully convinced that the glove in no way inconveniences or interferes with the operator's work. He says it must be admitted that the teacher and clinician are doing all they can to spread abroad the lessons of puerperal asepsis, but the duty yet devolves upon the profession at large, not only to practice but to preach them.

[1] Med. News, Oct. 10, 1903, p. 692.

OBSTETRICAL ANESTHESIA.

In the same paper Dr. Green says that modern civilization seems to have developed a type of woman who is incapable of bearing the pain of physiological labor. Ether and chloroform often produce uterine inertia, necessitate operative intervention and also predispose to post-partum bleeding. Medullary narcosis he does not regard as a safe and effectual method of relieving the pain of labor. With a mixture of scopolamine hydrobromate and morphia nitrate combined so that ten minims contain $\frac{1}{100}$ gr. of the former and $\frac{1}{4}$ gr. of the latter, administered by subcutaneous injection, he has had experience in sixteen primiparous cases and three multiparous. The cases are reported in detail. As a result of his observations, he says it would seem as if we have a valuable addition to obstetrical therapeusis, the good effects being very marked in primiparæ, but there was no apparent benefit in the few multiparous cases. The mixture was especially serviceable in nervous, excitable and hyperesthetic primiparæ, and the best results are obtained when the drugs are given early in the first stage, as soon as symptoms of nervous irritability manifest themselves.

ECLAMPSIA.

In respect to the treatment of eclampsia, Dr. Green makes no attempt to review the many therapeutic measures that have been found of more or less value, but he speaks briefly of the value of hyoscine (scopolamine) combined with morphine as a means of controlling convulsions, and the extreme nervous excitability observed in certain cases.

He says that ether and chloroform have proved

efficacious in controlling convulsions when promptly administered before the seizure actually occurs; chloral alone or combined with bromides is serviceable in mild cases and as an adjuvant to other sedative measures; Stroganoff's combined use of morphia and chloral has been successful in the experience of some observers. From his recent experience he believes that in hyoscine and morphia in heroic doses we have a potent agent for the control of extreme restlessness and maniacal excitement. He reports three successful cases which have recently been under his care in primiparæ. He begins by giving scopolamine $\frac{1}{100}$ of a gr. and morphia $\frac{1}{4}$ of a gr., repeated in a short time if necessary. These three cases all recovered, and for further details in the treatment the reader is referred to the original article.

TREATMENT OF PUERPERAL FEVER.

Fehling[2] of Strassburg says he believes that collargolum, in intravenous injection, is of value. He has used a sterile 2% solution without ill effects; amounts 2½ to 5 dr. being injected with a fine needle into a vein in the arm. The results varied; some charts showed an immediate fall in pulse and temperature, sometimes a very considerable one, and it is especially noteworthy that this was also accompanied by an improvement in the patient's condition. When the temperature rose again, fresh injections were made, these being often administered daily for eight or ten consecutive days. A permanent fall of temperature occurred once after one injection.

There were some fatal cases even with the injection. In other cases the fatal termination was postponed, as in a case of pyemia with numerous pulmonary abscesses. The remedy seems to lower the temperature and the pulse, and it has a certain value in diagnosis in addition to its good effect upon the patient.

TREATMENT OF PLACENTA PREVIA.

Hammer[3] reports 107 cases from the Wurtzburg Clinic, 19 cases of central insertion, 70 of lateral insertion and 18 of deep-seated placenta. The total mortality among the mothers was 8, or 7.47%, while the fetal mortality was 58, or 54.2%. In cases of placenta previa centralis, Hicks' method of combined version was performed in 14 instances, with 13 maternal recoveries, and with 3 living children. In lateral placenta previa, combined version was performed 40 times with 34 maternal and 13 fetal recoveries. In breech presentations, slow extraction was followed 8 times, with 7 fetal deaths. Artificial rupture of the membranes was practiced 11 times, with 10 fetal deaths. Perforation was necessary but once. In 2 cases metreurysis was done, saving both mother and child. The mortality for both mother and child is lower in cases of deep-seated placenta when rupture of the membranes was the treatment followed. The author calls attention to the impossibility of always being able to perform combined external and internal version without the aid of anesthesia.

[3] N. Y. Med. Journ., Oct. 17, 1903, p. 769. Muench. med. Wochenschrift, Sept. 1, 1903.

TUBAL PREGNANCY.

Chase[4] especially dwells on the importance of the general practitioner examining a woman liable to pregnancy bearing in mind the possibility of tubal pregnancy. He says the time has come when such cases will be reported with increasing frequency until the diagnosis in suitable cases becomes recognized as an essential duty of the well-qualified physician. In case it occurs and rupture has not taken place, the sooner the pregnant tube can be recognized and removed the better. In the cases in which the condition points to recent rupture of the intraperitoneal variety and evidences of hemorrhage are present, immediate operation should be done. If evidence is present that the rupture is extraperitoneal — into the broad ligament — and the resulting hematoma is moderate in size, waiting for developments may be justified, as nature may possibly take care of the mass. Finally, while it will continue to happen that ectopic pregnancy will show a very high mortality where no accurate diagnosis has been made until too late, it is true that with a proper appreciation of the grounds on which at least a presumptive diagnosis can be made by the practitioner, an increasing number of lives can be saved.

COMPARISON OF THE SIZE OF THE FETUS AND THE MATERNAL PELVIS.

Lane[5] has made in a considerable number of cases measurements of the maternal pelvis and compared them with measurements of the fetal head and with the fetal weight. The children were weighed and measured at birth, while the maternal pelvis was measured about ten days after labor, as he says owing to relaxation of the soft parts, this appears to be the most favorable time.

He comes to the conclusion that, except in the case of small pelves, there is a parallelism between the size of the child's head (and in particular of the biparietal diameter) and the conjugate diameter of the mother's pelvis, and is the result of natural growth, and is not a pressure phenomenon. The weight of the child, and therefore the size at birth, bears a definite relationship to the size of the mother's pelvis, and this relationship is carried so far that the biparietal diameter of the child increases correspondingly with the conjugate diameter of the pelvis through which it will ordinarily pass at birth. This, he states, may be summed up in the form of a law stated thus: "The child grows in utero in such a manner and at such a rate that at full term his size is proportioned to that of the mother's pelvis through which he has to pass in order to be born."

He also says that hereditary influence appears to have a far greater influence in determining

[4] Brookline Med. Journ., July, 1903, p. 312.
[5] Lancet, Sept. 26, 1903, p. 885.

the size of the child than any of the causes commonly recognized and mentioned, such as the sex, the age of the mother, the number of the pregnancy, or the stature, constitution and health of parents, or even the prolongation of pregnancy.

He further says it is to be noted that the application of this law of proportion receives a tacit acknowledgment in the case of the progeny of different races, but it is the application to individuals which is new.

MATERNAL CIRCULATION IN PREGNANCY.

Nicholson [6] says that there are certain normal changes which occur in the quantity and quality of the blood in pregnancy, and that under normal conditions arterial tone is regulated by the vasomotor center. But there is abundant clinical and experimental evidence to prove that the arterial caliber is influenced in a most profound manner by the internal secretions of the suprarenal and thyroid glands. Suprarenal extract contracts the arterioles very greatly, while the thyroid secretion has been proved to act in the opposite way.

These two internal secretions have opposing and contradictory effects upon the circulation, and in health a balance is struck between them. In normal pregnancy, on the other hand, there are frequent periods during which one or the other gains the upper hand. In general, at the beginning of pregnancy, the functional activity of the thyroid is increased, with resulting dilatation of blood vessels, rapid pulse, palpitation and stimulation of the metabolic processes of the body. If albuminuria is present, it has no grave significance. Other women, usually primiparæ late in pregnancy, will show too pronounced signs of suprarenal influence, as contraction of arteries, diminished metabolism, elevation of blood pressure, decreased urea excretion, etc. These patients are liable to develop eclampsia, and it is of the greatest pratical importance to recognize the high-pressure pulse as an early clinical symptom of impending danger. There should be no doubt as to treatment, the arterioles must be relaxed. In emergency, morphine, aconite and veratrum viride or infusion of saline solution will bring it about. For the pre-eclamptic symptoms, as persistent headache, vomiting and diminished secretion of urine, he has administered thyroid extract to a sufficient number of patients to be convinced of its value.

TREATMENT OF HEMATOCELE FORMED AFTER EXTRA-UTERINE PREGNANCY.

Zweifel [7] remarks that in a pregnant woman a sudden peritonitic attack — great abdominal pain, syncope, vomiting and a very small pulse, without fever, a rupture of a pregnant tube must be at once suspected and immediate operation must be performed. If, however, a hematocele is formed, expectant treatment is to be followed, for in the greater majority of instances the hemorrhage will cease and with rest in bed and with symptomatic attention to the pain and to constipation, the transudate will eventually be absorbed. Should it become infected, it is to be opened and drained from below. In the case of women who are obliged to work and who cannot remain in bed for some time, the hematocele may be opened through the vagina, but Zweifel says he always explains to them that they can be cured without operation.

THE CONDITION OF THE PELVIS IN WOMEN AFTER SYMPHYSIOTOMY.

Tissier [8] reports the after-histories of twenty women who had been delivered by symphysiotomy, during the period of five years. These cases were operated on at seven different hospitals. Only four out of the twenty escaped without some undesirable sequelæ, the remaining sixteen being all more or less damaged by the operation. One patient has been a chronic invalid for five years. Eight have suffered from phlebitis. Ten have had urinary troubles during months or years, incontinence of urine being the most common urinary affection. As a rule, this condition improves with time, but reappears on exertion or with a coughing effort. A number of women have difficulty in efforts of lifting, or in going up stairs.

ARTIFICIAL ABSCESSES IN THE TREATMENT OF PUERPERAL SEPSIS.

Since the method proposed of producing artificial abscesses by the subcutaneous injection of turpentine in septic cases, reports have from time to time appeared of cases successfully treated in this way. Hoff [9] adds two more to the list. The first was a primipara, with fever on the second day after a normal delivery. She grew worse, and on the ninth day he injected 2 cc. turpentine in the thigh. Abscess development showed in two days, and there was slight improvement both in temperature and general condition. The injection was repeated twice, when the improvement became continuous.

The second case was also a primipara with a dry operative labor. Turpentine injections were made on the eighth and eleventh days, and the patient improved steadily till the twenty-fourth day, when the temperature again rose, and two days later she had again a severe rigor. She had bloody urine, but a third injection of turpentine was made. The improvement was resumed and continued. It is stated that it is not very safe to reason from two cases as to the efficacy of any mode of treating puerperal sepsis, but both of these cases were fairly severe with temperatures up to 106° F., and they are enough to attract attention. It is suggested that the abscesses may be local producers of antitoxins or of leucocytes. The method is rather painful and a preliminary injection of morphia is advisable.

Reports of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

NINETY-EIGHTH ANNUAL MEETING, HELD IN ALBANY, JAN. 26, 27 and 28, 1904.

(Concluded from No. 8, p. 217.)

(SECOND DAY — *concluded.*)

ALGERNON T. BRISTOW, M.D., of Brooklyn, president.

DIAGNOSIS AND TREATMENT OF GLAUCOMA.

DR. D. B. ST. JOHN ROOSA of New York said that the physician should be on the alert for glaucoma when a person of middle age, or older, came complaining of neuralgia of the eye and dimness of vision, and examination showed a weeping conjunctiva and an area of redness around the cornea without adhesions of the eyelids. The diagnosis became positive if the tension of the eyeball were increased and the use of eserin solution relieved the pain. Aside from the use of eserin, the treatment rested with the specialist.

A STUDY OF THE CLIMATE OF LONG ISLAND.

DR. W. H. ROSS of Brentwood, L. I., read a paper with this title. In it he gave the results of his studies of the meteorological conditions for a period of ten years. The mean summer temperature was 70° F., and the annual range 39°. The relative humidity was low, the yearly average being 72.75. The average number of clear or partly clear days in the year was 300. In addition to these manifest advantages, there was on Long Island a tract of pine forest, six miles wide and sixty miles long. The island was essentially a pier extending a hundred miles into the Atlantic Ocean.

THE TREATMENT OF CANCER BY ITS OWN TOXIN.

DR. P. J. MCCOURT of New York said that this paper was supplementary to one which he had written in 1899. He laid stress on the necessity for avoiding all alcoholic stimulants and partaking of meat very sparingly, and asserted that in 90% of the cases in which this treatment had been tried (the number of cases not being stated) the administration of the toxin was followed by general improvement and decided prolongation of life; also that in 14% indurated glands had become normal, ulcers had healed, and the patients appeared to have been cured, both objectively and subjectively.

ELECTRIC GRAFTING.

DR. J. S. WIGHT of Brooklyn read a paper, in which he referred to certain facts regarding radioactivity and radiotherapy, and, among other things, described what he called "electrical grafting." The method consists in making the surface to be grafted sterile, and then curetting it. While still oozing the grafts are applied, and then, by means of the high-frequency discharge from a pointed electrode, clotting is induced, and the grafts are thereby firmly fixed upon a dry surface. After sponging away the exuded serum the area is dressed with 3% carbolized vaseline.

TUBERCULOUS MYOSITIS.

DR. WILLIAM B. BRINSMADE of Brooklyn reported a case of this very rare disease. The patient, an apparently healthy woman, had been struck, five months before, on the outer aspect of the leg. The examination pointed to a probable diagnosis of sarcoma, but a microscopical examination of a section showed typical tuberculous inflammation. Incision into the affected area revealed soft and pale muscular tissue studded with grayish areas, which, on section, were found to contain the typical caseous material of tuberculosis. This operation was done four months ago, and the patient at the present time continued to enjoy good health.

THE NON-OPERATIVE TREATMENT OF TRACHOMA.

DR. FRANK J. PARKER of New York believed that the operative treatment of trachoma should only be employed in the soft follicular variety, and then chiefly as a means of abridging the period of treatment. The non-operative treatment recommended by him consisted in the vigorous rubbing of the lids three times a week, under cocaine, with a 1 to 500 solution of bichloride and the use at home, twice daily, of a 10% solution of protargol or, preferably, of a solution of argyrol.

APHASIA AND AGRAPHIA.

DR. EDWARD D. FISHER of New York differentiated the various form of aphasia and agraphia, and expressed some doubt as to the correctness of the view that the writing center was located in the second frontal convolution, for the reason that cases were on record in which a lesion of this region did not cause agraphia. There was no doubt, however, about the close relationship between the speaking and writing centers, as shown clinically by the fact that agraphia and aphasia usually coexist.

SYMPOSIUM ON ABDOMINAL PAIN. ABDOMINAL PAIN IN GENERAL.

DR. JOHN H. MUSSER of Philadelphia, Pa., presented this paper. He pointed out that one might not find rigidity of the abdominal muscles in persons with relaxed abdominal walls, even though abdominal pain were present, and that, on the other hand, there might be exaggerated muscular spasm in very muscular individuals though the intra-abdominal condition were a trifling one. Sometimes in pregnant women the occurrence of pain in the upper half of the abdomen ushered in an attack of uremia. In diagnosing abdominal pain, one must remember diaphragmatic pleurisy and diaphragmatic rheumatism; also that in some cases of pneumonia, particularly in children, the signs might point very strongly to an appendicitis. Pyloric spasm might be confounded with gall-bladder disease. In his experience, nearly every case of supposed gastralgia had turned out to be cholelithiasis. The sudden disappearance of pain was often of grave significance, as pointing to profound toxemia.

ABDOMINAL PAIN REFERRED TO THE ABDOMINAL WALL.

DR. JOSEPH D. BRYANT of New York dwelt upon the importance of a knowledge of the nervous supply of the abdominal walls as an aid in diagnosticating pain referable to these parts. For instance, he said, involvement of that portion of the pleura supplied by the dorsal nerves would sometimes give rise to hyperesthesia and rigidity of the abdominal walls. Of course, a lesion confined to the abdominal wall might be mistaken for an intra-abdominal one.

ABDOMINAL PAIN OF INTESTINAL ORIGIN.

DR. FREDERICK HOLME WIGGIN of New York said that, generally speaking, a sharp persistent pain in the abdomen suggested peritoneal inflammation,

period of his greatest usefulness and for the stupid reason that the 'plum should be passed around.'"

HEALTH OF IMPERIAL JAPANESE NAVY.

WE are in receipt of the annual report of the Health of the Imperial Japanese Navy for the year 1901, published, however, in December, 1903. We call attention to this document, not so much because it contains information of great general value as for the reason that it shows the extraordinary care and devotion to detail which is characteristic of this nation, and some of the results of which have recently been seen. The report shows that the mean daily force in the service for the year under consideration was 26,469 persons, being an increase of upwards of 3,000 over the preceding year. Owing to this expansion of the navy there was a slight increase in the number of cases of disease as compared with the preceding years, and it also shows that the general ratio of men sick gives a certain decrease. The total number of cases of disease or injury was nearly 25,000, with an increase of day's sickness, as compared with previous years, due to the increase of the navy since the Japan-China war, and also to a revision of the regulations which has led to an inclusion of milder cases on the sick list than was before the custom. The statistics on this subject of illness in the navy are worked over with very great detail and should prove of interest to the statistician, if not to the general reader.

Following this general statement a summary of disease and injury is appended which covers a very wide range of conditions. This section of the report might be taken as a model for such work anywhere. It is evident that each disease is studied most carefully in all its relations, and therefore it becomes possible to prevent in a measure its occurrence, and thereby keep the navy in a state of high physical efficiency. It is of interest to note that cases of pulmonary tuberculosis occur with great frequency, and tend to increase in spite of preventive measures.

The report consists essentially of statistics, which it is not our purpose to reproduce. We merely desire to call attention at this time to the careful system for the tabulation of disease prevailing in the Japanese navy, which serves also to illustrate the general attitude of preparedness which has characterized all the acts of the Japanese during the events of the past few weeks.

MICROBES IN BOOKS.

A VALUABLE article on microbes in books was recently contributed to the *New York Times Saturday Review of Books* by Dr. Andrew F. Currier, who, although practicing as a gynecological specialist in New York, resides in the neighboring town of Mount Vernon and is president of the board of trustees of the public library there. He states that a great many more cases of the transmission of infectious disease through the medium of books in libraries have probably occurred than have been recorded, and that tuberculosis and scarlet fever have been thus acquired to his own knowledge. Having mentioned that in 1896 Dr. John S. Billings determined that infectious germs in books could be destroyed by the vapor of formalin, and referred to the experiments of other investigators, he said that it was only comparatively recently that a disinfecting apparatus had been devised which could be utilized by public libraries. This, which originated with himself, he describes as follows: To a steel cabinet with heavy plate-glass doors, as nearly airtight as possible, with a capacity for about 250 duodecimo volumes, is attached a generator by means of which formalin vapor is introduced, also another generator for the introduction of ammonia. As the books will not absorb all the formalin introduced, the ammonia is injected to combine with the residue of formalin. While formalin alone is an irritant to the mucous membranes, it is non-irritant when combined with ammonia. The apparatus is not complicated, and can be operated by any one with ordinary intelligence. Having stated that it was thoroughly tested last year under the supervision of the New York Board of Health, Dr. Currier says that it has now been in use for nearly two years at the Mount Vernon Public Library, and has worked satisfactorily, one of the most important results being the establishment of confidence on the part of the public in the innocuousness of the books which are circulated.

MEDICAL NOTES.

LOSS OF THE JOHNS HOPKINS HOSPITAL AND MEDICAL SCHOOL. — As a result of the recent Baltimore fire the resources of the Johns Hopkins Hospital and Medical School are temporarily somewhat seriously curtailed. It is said that the annual income will be diminished about $60,000, owing to the loss of rentals from buildings destroyed by the fire.

PERILS OF HAND SHAKING. — According to

American Medicine a Belgian savant has just published a treatise on shaking hands, which he states is most dangerous, a mutual pressure of the hand being nothing more than an exchange of undesirable microbes, 80,000 of which inhabit every half-inch of the hand. The most dangerous people to shake hands with, it appears, are doctors, surgeons, nurses, hairdressers, butchers, sausage-makers, tripe merchants, tanners and leather-dressers, while the least dangerous person seems to be a worker in metal, because the metal sets up an oxidation which acts as an antiseptic. The safe course is to salute only with our heads and our hats, or always wear gloves.

A Centenarian. — Noah Raby, who claimed to be the oldest man in the world, died on March 1 in the poorhouse of the Piscataway Township, N. J., of which he had been an inmate for nearly forty years. According to his own statement, had he lived to April 1 he would have been one hundred and thirty-two years old, but as there are no records to substantiate this claim, it is probably much exaggerated. He gave the place of his birth as Eastontown, N. C., and said his father was an Indian, while his mother was a white woman. It was his proud boast that he had used tobacco for over one hundred and twenty years. Some two or three years ago he had an attack of measles, and since then he has been totally blind.

Result of Two Lorenz Operations. — Dr. Harry M. Sherman, Professor of Surgery in the University of California, reports in a recent number of the *Journal of the American Medical Association* the results of two cases operated upon by Dr. Lorenz in San Francisco in November, 1902. In the first case the ultimate result did not lead to stable support of the pelvis on the femur, and could not from any point of view be regarded as a success. In the second case examination and radiographs showed conditions which likewise could not be regarded as an improvement. The careful observation of the cases operated upon by Dr. Lorenz, studied by the x-ray and otherwise, will no doubt give important, if not final, information regarding the efficacy of the so-called "bloodless operation."

The Twenty-Fifth Anniversary of the Cystoscope. — On March 9 was the twenty-fifth anniversary of the first demonstration of the cystoscope by Prof. Max Nitze. A committee consisting of Prof. Carl Posner, Dr. Hans R. Wossidlo and Dr. H. Goldschmidt of Berlin had been charged to arrange a celebration of the occasion. A part thereof was the presentation of an address, to which it was proposed to attach the signatures of those who have a general or special interest in genito-urinary diseases. The committee had asked Dr. Ferdinand Valentine of New York to obtain the signatures of those American colleagues who might desire to be thus represented in the address. A congratulatory cablegram preceded them, to the following effect: "Your colleagues and pupils congratulate themselves and the profession on the twenty-fifth anniversary of the demonstration of the cystoscope. Vivat Magister!"

Free Diphtheria Antitoxin in Chicago. — The Chicago Health Department is again prepared to furnish standard diphtheria antitoxin — from the bacteriologic laboratories of the New York Department of Health — to every physician of Chicago in the following manner:

(1) Physicians may obtain antitoxin free from the antitoxin stations of the department for the gratis treatment of their charity cases.

(2) Physicians may have their prescriptions for antitoxin to use in their paid practice filled by any antitoxin station at the following (present) prices:

No. 1 (1,000 units)	$0.75
No. 2 (2,000 units)	1.25
No. 3 (3,000 units)	2.25

Free antitoxin is furnished by the stations on the application of any physician who gives a receipt for the amount of antitoxin supplied, which receipt contains the following certificate: "I hereby certify that the family of this patient is unaole to pay for the antitoxin; that the case is urgent; that I am attending without fee and that I will report the termination of the case on the postal-card form of the health department furnished by the druggist."

In the body of the receipt is given the name of the patient and the exact residence address. This in order to refer what is, presumably, a case of destitution to the Bureau of Charities for such further assistance as, upon investigation, may be found necessary.

It is the object of the department to establish antitoxin stations so located as that there will be one within half a mile of every physician's office or residence, and so prevent unnecessary delay.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, March 2, 1904, there were reported to the Board of Health of Boston

while a dull aching pain pointed rather to involvement of the connective tissue. Tenesmus indicated a lesion of the lower third of the intestinal tract. A diagnosis of appendicitis should never be made until after a careful exploration had excluded disease of the lungs and pleura. When a patient complained of severe pain about the umbilicus, associated with constipation and collapse, one should search the various hernial openings, not forgetting to look for a tumor in the linea alba.

DR. R. F. WEIR of New York directed attention to the new method of examination brought forward by Dr. Ellsworth Eliot of New York, *i. e.*, the determination of the comparative resistance offered by the costal arches on the two sides. With the thumbs directed toward the sternum, the fingers should crowd the costal arches inward toward the vertebral column. An abnormal resistance was often encountered in lesions of the liver, pancreas, duodenum and pylorus. It was now well known that McBurney's point did not accurately represent the location of the vermiform appendix; nevertheless we owed much to McBurney for having pointed out the value of "finger pressure" in eliciting the peculiar tenderness found with appendicitis. When difficulty was experienced in palpating the appendix, the examination could sometimes be facilitated by directing the patient, while in the recumbent posture, to raise the leg and abduct it a little, thus putting the psoas muscle on the stretch, and bringing the appendix nearer the palpating finger.

THIRD DAY, THURSDAY, JAN. 28.

OFFICERS.

The following were elected: President, Dr. Hamilton D. Wey of Elmira; Vice-President, Dr. Joseph D. Bryant of New York; Secretary, Dr. F. C. Curtis of Albany; Treasurer, Dr. O. D. Ball of Albany.

A CASE OF RECURRING MEMBRANOUS STOMATITIS ASSOCIATED WITH ERYTHEMA EXUDATIVUM MULTIFORME (HEBRA).

DR. LOUIS E. BLAIR of Albany reported this remarkable case. The skin affection did not appear until a week after the stomatitis. It remained for a month and left copper-colored spots that were visible for a long time, and were finally succeeded by white contracted scars. The membranous exudation in the mouth was firmly adherent, and a similar deposit appeared coincidentally on the mucous membrane about the anus and glans penis.

THE HOSPITAL CAR; ITS EQUIPMENT, USE AND IMPORTANCE.

DR. W. W. SANFORD of New York described the modern hospital car. The one taken as an example was sixty feet long, was practically dust-proof and was finished entirely in white. The car was divided into two compartments, — a smaller, or accident ward, and an ordinary hospital ward. He urged the importance of the medical advisers of railroad companies using their influence to secure the more general introduction of such cars.

SYMPOSIUM ON NEPHRITIS. RENAL DECAPSULATION FROM THE PATHOLOGIST'S POINT OF VIEW.

DR. J. M. VANCOTT of Brooklyn was the author of this paper. He said that the blood supply of the kidney was an end-artery system, and that, with the exception of a few interlobular arteries and a few arteries entering the cortex, the only communication was through the capillaries. From this it followed that decapsulation subjected the parenchyma of the kidney to loss of nutrition, alteration of pressure and even reversal of the blood current — in other words, a condition usually found in connection with renal infarction. Litten's experiments had demonstrated that the collateral circulation was not capable of restoring the equilibrium of the circulation after decapsulation. It should not be forgotten that when the capsule was torn away, the vessels which usually restore the circulation were destroyed, and that only the capillaries were left. Again, there must be death of considerable portions of the renal parenchyma, because the renal epithelia die in two hours after being deprived of their blood supply, and it required at least four days for the formation of new capillaries. No amount of restoration of the renal circulation could restore the integrity of the cortex. From these facts it followed that decapsulation was positively injurious to the normal kidney and of no benefit to the large white kidney.

SURGICAL TREATMENT OF NEPHRITIS.

DR. WILLIS G. MACDONALD of Albany spoke extemporaneously on this topic. He was inclined to believe that in infectious nephritis, due to local infection with such germs as the gonococcus and the streptococcus, surgery should be of some benefit. In those cases in which suppression of urine followed within thirty-six hours after an operation on the genito-urinary tract, and which almost always terminated fatally under medical treatment, surgery could hold out more hope. By way of illustration, he reported a recent case of this kind in which, after forty-eight hours of suppression of urine, incision of the capsule of the kidney quickly re-established the flow of urine.

GENERAL TREATMENT OF NEPHRITIS.

DR. BEVERLEY ROBINSON of New York said that, in the treatment of acute diffuse nephritis, two cardinal principles of treatment were physiological rest of the diseased part and the removal of some of the strain on its functional capacity by invoking the action of the skin and bowel. At first the patient should have an exclusively milk diet, but after a few days, gruels, jellies and amylaceous articles might be added and the patient should be encouraged to drink freely of spring water. When there was much edema or dyspnea, a saline purge should be given and the skin excited to activity by a hot wet pack. This he very much preferred to the hot-water bath or, in private practice at least, to the hot-air bath, because of its simplicity, effectiveness and freedom from risk. When the urine was scanty and highly albuminous and there was pain over the kidneys, congestion of the kidneys might often be diminished by the application of mustard poultices. High rectal irrigations with Kemp's tube were also useful in promoting diuresis. He had known pilocarpin to cause fatal bronchitis, and considered it too dangerous a drug to use. To avert an attack of uremia he would give nitroglycerin and sweet spirits of niter and, if the case were sufficiently urgent, would resort to wet-cupping or to venesection. For the control of convulsions, chloroform might be required, and occasionally morphine, but he was reluctant to use the latter, particularly in chronic nephritis. For the severe anemia following nephritis, tincture of the chloride of iron, or the tonic diuretic compound known as Basham's mixture, was useful. If the albuminuria should persist, the physician should endeavor to improve the general health, and should carefully regulate the diet and bowels and restrict the amount

of physical effort. The diarrhea of Bright's disease could often be well controlled by prolonged irrigation of the bowel. When the anasarca was extreme it might be necessary to puncture the skin in several places, or even insert a small capillary drainage tube. Incisions should be made and the parts dressed under aseptic precautions. Severe dyspnea might, of course, call for paracentesis of the thorax or of the abdomen. In persons past middle life, digitalis could rarely be safely given unless guarded by nitroglycerin. In chronic cases the importance of even slight subacute attacks of nephritis must not be lost sight of. When the nephritis was due to some underlying constitutional taint, such as syphilis, it was tempting to give iodide of potassium, but although there was high authority for such treatment he had always felt disposed to use this drug rather charily because of its irritating action on the kidney. In the medicinal treatment of persons suffering from nephritis it was well to remember that drugs like the salicylates and the phenol derivatives were usually out of place, because of their known irritant action upon the kidneys. These patients were, as a general rule, better off without alcohol in any form, but in persons who had been accustomed to take alcoholic drinks in moderate quantities for many years he would not adhere too closely to this rule, but would insist that only small quantities be taken, and always with the meals and well diluted. For sleeplessness he preferred the bromides to chloral. With regard to morphine in uremia, he would again insist that while it appeared to be useful in cases characterized by a dilatation of the pupil, it was decidedly dangerous to use it where the contrary state of the pupil prevailed.

Dr. DeLancey Rochester of Buffalo said that in cases of acute suppression of urine he was sure just as good results could be obtained from cupping and leeching of the loin and venesection as from any surgical treatment. He was a firm believer in the efficacy of the hot-air bath, and he had often given it easily and effectively in the humblest homes by making use of two barrel hoops, an "elbow" of stovepipe and an alcohol lamp. If diaphoresis were not easily excited, he gave minute doses of pilocarpin hypodermically, always following this immediately by the hot-air bath. When convulsions threatened, he would give a moderate dose of morphin and follow this by the hot-air bath. In subacute nephritis, the daily washing out of the bowel with saline solution and allowing some of the solution to be retained was a useful measure.

Dr. S. B. Ward of Albany spoke of the great benefit to be derived from the use of arsenic in overcoming the severe and obstinate anemia of nephritis.

THE OBSTETRICAL SOCIETY OF BOSTON.

BY MALCOLM STORER, M.D., SECRETARY.

Meeting of Nov. 17, 1903, the President, Dr. J. B. Swift, in the chair.

Dr. E. B. Young, by invitation, read a paper entitled

THE RUPTURE OF OVARIAN CYSTS.[1]

Dr. W. F. Whitney: At the autopsy table I frequently see cysts, the walls of which contain scars of old ruptures where there were evidently no bad consequences. I remember one case in which there were two large papillary masses entirely uncovered by cyst wall. The wonder is that rupture does not take place more often. Any large cyst has many thin places in its wall apparently ripe for rupture.

[1] See page 235 of the Journal.

Dr. T. M. Rotch: As an example of the possible bad effect of the rupture of very small cysts I can recall a case of death from septic peritonitis following the rupture of a cyst no larger than a pea.

Dr. L. V. Friedman: I remember the rupture of a cyst the size of an egg with no symptoms. As regards the strength of the cyst wall in the preparation of some specimens for the museum I found that cysts would stand much greater tension without rupture than they were probably ever subjected to during life.

Dr. M. Storer: The case which I reported to this society some years ago was briefly that of a young woman whom I allowed some graduate students to examine under ether, in whom I had found an ovarian tumor the size of a man's head. The third examiner ruptured it. Within ten minutes it had been removed, yet during that time the abdomen was pretty well filled with blood from a large vessel torn across at the point of bifurcation. Oddly enough only the other day I was speaking to my students at the dispensary about that case, and the very next case I examined, a very thin-walled woman, had an ovarian tumor the size of two fists, which collapsed under my fingers with only very gentle pressure. She was not conscious of anything happening and the only symptom that followed was menstruation coming on next day, ten days ahead of time, the first time that it had ever happened with her.

I remember being very much perplexed over my first dissecting-room subject, an immensely large woman. On operating the peritoneal cavity I came upon a soft white membrane that proved to be the collapsed wall of a cyst that when full must have weighed fifty pounds at least. I am somewhat surprised at the views Dr. Young has expressed about the results of operating upon ovarian tumors during pregnancy. I have only happened to operate on two cases during pregnancy, once with torsion at six months and once at three months. The pregnancy was not affected in either case. My reading has rather inclined me to feel that pregnancy is an indication for operation rather than otherwise.

Dr. C. H. Hare: I have seen two cases of rupture. The first was a case of Dr. Burrage, in which the cyst was probably ruptured by the nurse preparing the patient for operation the night before. An acute peritonitis was found and the patient died. The second case I operated upon a week ago, twelve hours or so after rupture. A double torsion was present and probably was the cause of rupture. This patient has done well thus far.

Dr. F. A. Higgins: Dr. Green will remember a case seen by several students some years ago. Under the hands of one of them the cyst suddenly disappeared. There were no symptoms.

Dr. J. C. Hubbard read upon the

ETIOLOGICAL IMPORTANCE OF INTESTINAL PARASITES IN APPENDICITIS.

Dr. Whitney: Intestinal parasites in the appendix must be very rare in this part of the world. I have found pin worms only twice and ascaris once, — in this case.

Dr. A. Worcester questioned the value of a vermifuge having any influence on parasites that were hidden away in the appendix.

Dr. Rotch: There is no question but that vermifuges are of great value in many cases when the parasite is in the upper intestine where enamata are of no effect. The giving of vermifuges by the mouth might accordingly have some use in preventing parasites from getting into the appendix.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MARCH 3, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

BACILLUS PRODIGIOSUS.

DURING the last fifty years, the Bacillus prodigiosus has been the subject of many investigations, made from different points of view. The results have been accepted, often without confirmation, and used as a basis for argument or put down in textbooks as facts. Recent investigations, carried on in Turin by Dr. E. Bertarelli,[1] suggest that some of our ideas regarding this micro-organism will have to be modified.

Dr. Bertarelli gives his earlier experiments in detail, summarizing as follows: The prodigiosus causes a fatal toxico-septicemia when inoculated in moderately high doses into animals, especially the guinea pig, rat and mouse. The postmortem appearance of an animal thus treated shows an overwhelming intoxication. By means of the microscope and cultures one observes the undoubted presence and multiplication of prodigiosus in the blood and organs, including those of the embryo. Furthermore, in the passage through an animal, the prodigiosus reacquires, if unpigmented, its red pigment, and this even when one is unable to bring back the characteristic pigment by cultivation on potato. If already pigmented, the culture may even acquire the power of remaining pigmented at 37° C. He uses an intraperitoneal inoculation into a guinea pig of about 2 cu. cm. of a bouillon culture five days old to demonstrate to students a typical septicemia. The virulence of the culture can be increased by passing it through a series of animals in a collodion sac in the abdominal cavity.

[1] Archiv. per le Scienze Mediche, 1903, xxxvii, 1, pp. 1–31.

Further experiments to show how the toxic effects are produced prove that the toxicity of the prodigiosus is specially bound to the bacterial cell; that the soluble products are only slightly toxic, but have hemolytic and chemiotactic properties; that the protein extracted by the method of Koch possesses a toxic power analogous to that of the dead bacilli; and, finally, that the nucleo-proteid, even deprived of the nucleo-istone, is capable of moderate toxic action. The results of the intoxication by prodigiosus ought not, therefore, to be attributed in a special manner, as some authors wish, to trimethylamin or other product of the metabolism of the germ, but are intimately connected with the bacterial cell itself. The prodigiosus will resist a temperature of 80° C. for an hour before being killed.

Coming now to the association of prodigiosus with some other organism, especially streptococcus and the bacillus of anthrax, Bertarelli gives details of further interesting experiments. Inoculation of a mixture of streptococci and staphylococci does not kill an animal except in very large doses. When, however, the mixture is followed by inoculation of sufficient prodigiosus culture (.8 cu. cm. for a guinea pig) the animal dies in twelve to twenty-four hours, and cultures from the blood show abundant prodigiosus and much smaller quantities of staphylococcus and streptococcus. Only when the streptococcus previously possesses a distinct virulence does one secure a very slight exaltation of its virulence by mixing it with prodigiosus — in such a case death is due to septicemia from streptococcus, with presence of this organism in the circulation, while the prodigiosus is very scarce or wanting.

Equal parts of anthrax and prodigiosus culture in dose of 1 cu. cm. of mixture caused death of the guinea pig in eighteen hours with presence of prodigiosus in circulation and very few colonies of anthrax. Another mixture of 1 cu. cm. anthrax and $\frac{1}{8}$ cu. cm. prodigiosus was followed by death of the guinea pig in forty-eight hours due to anthrax. In nearly all those inoculations where prodigiosus was added to anthrax the animals died later than controls inoculated with anthrax alone. There is a distinct antagonism between anthrax and prodigiosus, which can be demonstrated even better in the test tube. These experiments included attempts to immunize animals against prodigiosus (not an easy matter) and subsequent inoculation with anthrax. One such

animal survived thirty hours longer than the control. Further experiments along this line will probably show that so-called "non-specific" immunity is of less importance than previously supposed.

It is certain, therefore, that in the association of attenuated pathogenic organisms with prodigiosus, one ought to speak with great caution of the increase of virulence given by the prodigiosus, since in some cases such increase is absolutely wanting or is problematical, while on the contrary, as follows with anthrax, one can have a diminution of the effect of the infection even in animals so typically receptive as guinea pigs. It follows besides, from the results shown, that in the test tube the antagonism beween prodigiosus and anthrax is very marked.

He does not believe that by these observations he has modified the more essential data that many investigators have recorded on the biology of prodigiosus, and on the significance of the association of microbes; especially since the greater part of the experiments recorded (Roger, Klein, etc.) were done under special conditions. The result that has chief biological interest is the concept that prodigiosus, without being a pathogenic micro-organism, elaborates and possesses toxic substances in truly appreciable amount, and these introduced in distinct but not very great quantities into an animal can give rise to a true septicemia. On this account concepts generally set forth in treatises on prodigiosus ought to be modified in this respect — that the organism should be classed as harmless with regard to accidental infection, but distinctly toxic even without recourse to the very high doses which some authors record.

It is a great mistake to suppose from this, even for a moment, that prodigiosus can have any pathogenic importance for man. Not only is there no record of a fatal case, but it is sufficient to recall its enormous diffusion and the ease with which it comes in contact with us to remove every doubt. Bertarelli has inhaled and swallowed little masses of living bacilli without any effect. He could never produce symptoms by feeding a culture to animals or rubbing it into surface lesions.

Although the prodigiosus is harmless under ordinary conditions, nevertheless its biological properties, its toxicity, its peculiar behavior with other organisms, the pigmentation that it acquires in passing through an animal, are interesting facts which seem to be worth recording.

This addition to our knowledge has a practical application in connection with the mixture of prodigiosus and erysipelas toxins used more or less successfully by Dr. W. B. Coley for the treatment of inoperable sarcoma.

POLITICS AND PUBLIC HEALTH.

It is with much regret that we note in the *Wisconsin Medical Journal* of February last the retirement of Dr. U. O. B. Wingate from the position of secretary of the State Board of Health of Wisconsin. Dr. Wingate had been recognized for several years as a thorough sanitarian and an acknowledged authority upon subjects relating to public health. The *Wisconsin Medical Journal* alludes to the matter as follows: "Dr. Wingate's retirement is not in the interest of the people nor of the public health, nor is it due to any lack of fitness; political reasons only have dictated it. In the language of one of the political members of the State Board of Health, 'this plum should be passed around.'

"We know whereof we speak, when we say that the method of this retirement is discreditable to those members of the State Board of Health who manipulated the deal, discreditable to the state administration and unwarranted by Dr. Wingate's long and efficient conduct of the office. The public health is too vital a matter to be subjected to the vicissitudes of politics."

Instances of successful or of unsuccessful interference by politicians with the work of boards of health are unfortunately of too common occurrence in this country. Political bossism, Addicksism and the selfish greed of office-seeking too often result in the removal of competent officials at the period of their greatest usefulness. It is not necessary to turn backward many pages in the history of public sanitation to witness the practical abolition of the National Board of Health by the withdrawal of its appropriation in 1883; the ill-assorted union of health, lunacy and charity in Massachusetts in 1879, under the panicky fear of Butlerism; the recent overthrow of the health administration of Pittsburg; the unsuccessful attempt to depose a public sanitary official in Michigan. These were all illustrations of such unwise and harmful interference. "If," says the *Wisconsin Medical Journal*, "the politicians of this state were to grasp the force of these facts, and were to consult the best interests of the people, we should not again be treated to the spectacle of the underhanded removal of a thoroughly competent medical official at the

period of his greatest usefulness and for the stupid reason that the 'plum should be passed around.'"

HEALTH OF IMPERIAL JAPANESE NAVY.

WE are in receipt of the annual report of the Health of the Imperial Japanese Navy for the year 1901, published, however, in December, 1903. We call attention to this document, not so much because it contains information of great general value as for the reason that it shows the extraordinary care and devotion to detail which is characteristic of this nation, and some of the results of which have recently been seen. The report shows that the mean daily force in the service for the year under consideration was 26,469 persons, being an increase of upwards of 3,000 over the preceding year. Owing to this expansion of the navy there was a slight increase in the number of cases of disease as compared with the preceding years, and it also shows that the general ratio of men sick gives a certain decrease. The total number of cases of disease or injury was nearly 25,000, with an increase of day's sickness, as compared with previous years, due to the increase of the navy since the Japan-China war, and also to a revision of the regulations which has led to an inclusion of milder cases on the sick list than was before the custom. The statistics on this subject of illness in the navy are worked over with very great detail and should prove of interest to the statistician, if not to the general reader.

Following this general statement a summary of disease and injury is appended which covers a very wide range of conditions. This section of the report might be taken as a model for such work anywhere. It is evident that each disease is studied most carefully in all its relations, and therefore it becomes possible to prevent in a measure its occurrence, and thereby keep the navy in a state of high physical efficiency. It is of interest to note that cases of pulmonary tuberculosis occur with great frequency, and tend to increase in spite of preventive measures.

The report consists essentially of statistics, which it is not our purpose to reproduce. We merely desire to call attention at this time to the careful system for the tabulation of disease prevailing in the Japanese navy, which serves also to illustrate the general attitude of preparedness which has characterized all the acts of the Japanese during the events of the past few weeks.

MICROBES IN BOOKS.

A VALUABLE article on microbes in books was recently contributed to the *New York Times Saturday Review of Books* by Dr. Andrew F. Currier, who, although practicing as a gynecological specialist in New York, resides in the neighboring town of Mount Vernon and is president of the board of trustees of the public library there. He states that a great many more cases of the transmission of infectious disease through the medium of books in libraries have probably occurred than have been recorded, and that tuberculosis and scarlet fever have been thus acquired to his own knowledge. Having mentioned that in 1896 Dr. John S. Billings determined that infectious germs in books could be destroyed by the vapor of formalin, and referred to the experiments of other investigators, he said that it was only comparatively recently that a disinfecting apparatus had been devised which could be utilized by public libraries. This, which originated with himself, he describes as follows: To a steel cabinet with heavy plate-glass doors, as nearly airtight as possible, with a capacity for about 250 duodecimo volumes, is attached a generator by means of which formalin vapor is introduced, also another generator for the introduction of ammonia. As the books will not absorb all the formalin introduced, the ammonia is injected to combine with the residue of formalin. While formalin alone is an irritant to the mucous membranes, it is non-irritant when combined with ammonia. The apparatus is not complicated, and can be operated by any one with ordinary intelligence. Having stated that it was thoroughly tested last year under the supervision of the New York Board of Health, Dr. Currier says that it has now been in use for nearly two years at the Mount Vernon Public Library, and has worked satisfactorily, one of the most important results being the establishment of confidence on the part of the public in the innocuousness of the books which are circulated.

MEDICAL NOTES.

LOSS OF THE JOHNS HOPKINS HOSPITAL AND MEDICAL SCHOOL. — As a result of the recent Baltimore fire the resources of the Johns Hopkins Hospital and Medical School are temporarily somewhat seriously curtailed. It is said that the annual income will be diminished about $60,000, owing to the loss of rentals from buildings destroyed by the fire.

PERILS OF HAND SHAKING. — According to

American Medicine a Belgian savant has just published a treatise on shaking hands, which he states is most dangerous, a mutual pressure of the hand being nothing more than an exchange of undesirable microbes, 80,000 of which inhabit every half-inch of the hand. The most dangerous people to shake hands with, it appears, are doctors, surgeons, nurses, hairdressers, butchers, sausage-makers, tripe merchants, tanners and leather-dressers, while the least dangerous person seems to be a worker in metal, because the metal sets up an oxidation which acts as an antiseptic. The safe course is to salute only with our heads and our hats, or always wear gloves.

A Centenarian. — Noah Raby, who claimed to be the oldest man in the world, died on March 1 in the poorhouse of the Piscataway Township, N. J., of which he had been an inmate for nearly forty years. According to his own statement, had he lived to April 1 he would have been one hundred and thirty-two years old, but as there are no records to substantiate this claim, it is probably much exaggerated. He gave the place of his birth as Eastontown, N. C., and said his father was an Indian, while his mother was a white woman. It was his proud boast that he had used tobacco for over one hundred and twenty years. Some two or three years ago he had an attack of measles, and since then he has been totally blind.

Result of Two Lorenz Operations. — Dr. Harry M. Sherman, Professor of Surgery in the University of California, reports in a recent number of the *Journal of the American Medical Association* the results of two cases operated upon by Dr. Lorenz in San Francisco in November, 1902. In the first case the ultimate result did not lead to stable support of the pelvis on the femur, and could not from any point of view be regarded as a success. In the second case examination and radiographs showed conditions which likewise could not be regarded as an improvement. The careful observation of the cases operated upon by Dr. Lorenz, studied by the x-ray and otherwise, will no doubt give important, if not final, information regarding the efficacy of the so-called "bloodless operation."

The Twenty-Fifth Anniversary of the Cystoscope. — On March 9 was the twenty-fifth anniversary of the first demonstration of the cystoscope by Prof. Max Nitze. A committee consisting of Prof. Carl Posner, Dr. Hans R. Wossidlo and Dr. H. Goldschmidt of Berlin had been charged to arrange a celebration of the occasion. A part thereof was the presentation of an address, to which it was proposed to attach the signatures of those who have a general or special interest in genito-urinary diseases. The committee had asked Dr. Ferdinand Valentine of New York to obtain the signatures of those American colleagues who might desire to be thus represented in the address. A congratulatory cablegram preceded them, to the following effect: "Your colleagues and pupils congratulate themselves and the profession on the twenty-fifth anniversary of the demonstration of the cystoscope. Vivat Magister!"

Free Diphtheria Antitoxin in Chicago. — The Chicago Health Department is again prepared to furnish standard diphtheria antitoxin — from the bacteriologic laboratories of the New York Department of Health — to every physician of Chicago in the following manner:

(1) Physicians may obtain antitoxin free from the antitoxin stations of the department for the gratis treatment of their charity cases.

(2) Physicians may have their prescriptions for antitoxin to use in their paid practice filled by any antitoxin station at the following (present) prices:

No. 1 (1,000 units)	$0.75
No. 2 (2,000 units)	1.25
No. 3 (3,000 units)	2.25

Free antitoxin is furnished by the stations on the application of any physician who gives a receipt for the amount of antitoxin supplied, which receipt contains the following certificate:

"I hereby certify that the family of this patient is unable to pay for the antitoxin; that the case is urgent; that I am attending without fee and that I will report the termination of the case on the postal-card form of the health department furnished by the druggist."

In the body of the receipt is given the name of the patient and the exact residence address. This in order to refer what is, presumably, a case of destitution to the Bureau of Charities for such further assistance as, upon investigation, may be found necessary.

It is the object of the department to establish antitoxin stations so located as that there will be one within half a mile of every physician's office or residence, and so prevent unnecessary delay.

Boston and New England.

Acute Infectious Diseases in Boston. — For the week ending at noon, March 2, 1904, there were reported to the Board of Health of Boston

the following cases of acute infectious diseases: Diphtheria 50, scarlatina 26, typhoid fever 8, measles 146, smallpox 0.

LYNN, MASS., HOSPITAL. — The twenty-first annual report of the Lynn Hospital for the year 1903 indicates the increasing usefulness of the institution in every department. The average number of patients in the hospital daily was 59, and during the year 136 more were treated than in the preceding year. A similar increase occurred in the maternity department, where instead of 61 patients 81 were admitted during the year. The whole number of patients admitted during the year was 1,253, with 4,651 new patients treated in the out-patient department. This development of the hospital work has entailed increasing expenses, so that the expenditures have far exceeded the receipts. The need of still further enlargement of the hospital buildings is imperative, and a new ward building, begun in April, it is hoped will soon be completed.

NEW YORK.

NEW BUILDING FOR NURSES. — The managers of the New York Training School for Nurses, in connection with Bellevue Hospital, have purchased a lot 125 by 100 feet on East 25th Street for the erection of a new building. This is directly back of the present quarters of the school on 26th Street, opposite the hospital, and the new building will probably be extended eventually over the entire premises.

NEW BUILDING FOR ST. FRANCIS HOSPITAL. — The Sisters of the Poor of St. Francis, who for thirty-eight years have conducted St. Francis Hospital in East 5th Street, are erecting a new hospital building in the Bronx. The location is at 143d Street and St. Ann's Avenue, directly opposite St. Joseph's Hospital for Consumptives. There will be nineteen large wards, with 304 beds, and forty small wards, a number of which are to be used for private patients.

COMPLIMENTARY DINNER TO DR. ROOSA. — On March 1 a complimentary dinner was given at Delmonico's to Dr. D. B. St. John Roosa, in honor of the twenty-first anniversary of the founding of the New York Post-Graduate Medical School, of which Dr. Roosa has been the president since the beginning. It was attended by more than three hundred physicians and distinguished laymen, and a large loving cup of silver was presented to him on behalf of the faculty of the Post-Graduate School. Dr. William Osler of the Johns Hopkins University acted as toastmaster, and among the other prominent men from a distance were Drs. Clarence J. Blake and Maurice H. Richardson of Boston, Wm. W. Keen and John H. Musser of Philadelphia, and Wm. H. Welch and Howard Kelly of Baltimore. The Rev. Dr. Marvin R. Vincent made the loving cup presentation speech, and the other speakers, besides Dr. Roosa himself, were Drs. Osler, Keen, Blake, Polk of New York; and Mayo of Rochester, Minn.; and Mr. William Potter, a trustee of Jefferson Medical College, Philadelphia.

PUBLIC TUBERCULOSIS CLINIC. — The Health Department is now opening a public tuberculosis clinic, having had constructed for the purpose a convenient building adjoining the headquarters of the department at Sixth Avenue and 55th Street. The clinic includes a registration office, two waiting rooms, two rooms for general examinations, a throat room and an x-ray room. The examinations will be conducted by experts, and the first object aimed at is early recognition and correct diagnosis of cases of pulmonary tuberculosis. Patients will be supplied with circulars containing exact and intelligible instructions, and those in indigent circumstances will be given treatment and furnished with sputum cups, etc., free of charge. In addition, poor patients and those discharged from the public institutions of the city will be cared for at their homes and places of occupation by a special corps of trained nurses, and the cooperation of charitable organizations has been secured to supply food, fuel, ice and other articles where needed. One of the chief duties of these nurses will be to look after the children in the homes of consumptives, with a view to preventing their becoming infected. Suitable cases will be provided for in hospitals and many of those promising recovery sent to out-of-town sanatoria.

MORTALITY IN FEBRUARY. — The weekly reports of the Health Department show that the mortality in the city during the month of February represented an annual death-rate of 22.59, as against 21.22 in January and 20.81 in February, 1903. The corrected death-rate, excluding non-residents and infants under one week old, was 21.68. Among the diseases which showed an increased mortality were the following: The weekly average of deaths from diphtheria and croup increased from 51 in January to 54.75 in February; of deaths from

whooping-cough, from 1.5 to 3.25; from influenza, from 15 to 24.25; from pneumonia, from 226.5 to 263.25; from pulmonary tuberculosis, from 157.75 to 172.25; from diarrheal diseases, from 36.25 to 48.5; from diarrheals under two years of age, from 28 to 38.5; from Bright's disease and nephritis, from 137.25 to 139.5; and from organic heart diseases, from 108.25 to 118. Among the diseases which showed a decline in mortality were the following: The weekly average of deaths from bronchopneumonia decreased from 122.25 to 118.5; from acute bronchitis, from 56 to 49; and from cancer, from 56.5 to 49. The rise in the death-rate is due to a considerable extent to the increased mortality from influenza and pneumonia, and in the week ending Feb. 27 the deaths from the latter disease, exclusive of bronchopneumonia, numbered 328, as against 202 in the corresponding week of 1903. In this week the general death-rate reached 24.43. The total number of deaths in the city was 1,797, and in the boroughs of Manhattan and the Bronx (comprising the city before the consolidation of 1899), 110. This is a higher mortality than for any week of the winter season since the notable influenza epidemic of 1892–3. During the month of February there was one death from smallpox, as was the case in January.

Apartments for Physicians. — The statement has been published that the old Madison Avenue Hotel, at the corner of 58th Street and Madison Avenue, which has been unoccupied for several years, is to be remodeled and fitted up with apartments exclusively for physicians. The building is six stories high and covers a plot of ground one hundred by ninety-five feet.

Miscellany.

FOURTH OF JULY TETANUS.

At a meeting of the Berkshire District Medical Society, held Feb. 26, 1904, the following preamble and resolution was passed: *Whereas*, 406 deaths from tetanus were reported as occurring in the United States in July, 1903, as a result of the Fourth of July celebration, 363 of these deaths having been caused by toy pistols loaded with blank cartridges, and 17 by cannon crackers, and

Resolved, that the Berkshire District Medical Society is in favor of any legislation and municipal ordinances which will effectively stop the sale and use of toy pistols, blank cartridges and cannon crackers for such purposes and

. Swift, M.D., Secretary.

RECORD OF MORTALITY

For the Week ending Saturday, Feb. 20, 1904.

Cities.	Population Estimated, 1904.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported, 4,099; under five years of age, 1,056; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 836, acute lung diseases 1,028, consumption 440, scarlet fever 53, whooping cough, cerebrospinal meningitis 9, smallpox 15, erysipelas 15, puerperal fever 20, measles 38, typhoid fever 31, diarrheal diseases 112, diphtheria and croup 81.

From whooping cough, New York 4, Pittsburg 2, Providence 1. From smallpox, New York 1, Philadelphia 13, Pittsburg 1. From cerebrospinal meningitis, New York 3, Pittsburg 1, Boston 1, Lynn 1, New Bedford 2, Marlborough 1. From erysipelas, New York 5, Chicago 2, Philadelphia 3, Pittsburg 1, Boston 3, Pittsfield 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,475, for the week ending Feb. 6, the death-rate was 17.2. Deaths reported, 5,049; acute diseases of the respiratory organs (London) 190, whooping cough 173, diphtheria 48, measles 80, smallpox 1, scarlet fever 39.

The death-rate ranged from 6.0 in Smethwick to 26.6 in Wigan; London 17.4, West Ham 16.5, Brighton 17.8, Southampton 18.8, Plymouth 16.5, Bristol 14.4, Birmingham 16.1, Leicester 13.7, Nottingham 19.7, Liverpool 23.1, Bolton 19.9, Manchester 19.4, Salford 16.6, Bradford 14.6, Leeds 19.5, Hull 14.6, Cardiff 16.9, Rhondda 22.2, Hornsey 6.4, Merthyr Tydfil 22.2.

METEOROLOGICAL RECORD.

For the week ending Feb. 20, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

DELAYED PUBLICATION.—The strike among printers and pressmen is responsible for delays in issuing the JOURNAL.

SOCIETY NOTICES.

THE AMERICAN SOCIETY OF CLINICAL SURGERY.—This society, with a membership of about thirty-six, will meet in New York, March 18, at the College of Physicians and Surgeons, Columbia University, 437 West 59th Street, and will subsequently visit various laboratories and hospitals, March 18 and March 19.

SUFFOLK DISTRICT MEDICAL SOCIETY.—There will be a meeting of the Section for Obstetrics and Diseases of Women in Sprague Hall, Boston Medical Library Building, 8 The Fenway, Wednesday, March 23, 1904, at 8 P.M., for the election of a chairman for this section, to hear the report on the mail-vote recommended at the last meeting and for the presentation of the following papers:

(1) Dr. G. S. Whiteside.—"Demonstrations of the Casper-Hirschmann Cystoscope."

(2) Dr. Annie Lee Hamilton.—"A Case of Labor in an Epileptic."

(3) Dr. E. W. Cushing.—"Repair of Lacerations of the Perineum occurring during Childbirth."

W. H. GRANT, M.D., Secretary.

THE HENRY PHIPPS INSTITUTE INTERNATIONAL COURSE OF LECTURES.

THE fifth lecture in the International Course given under the auspices of the Phipps Institute will be delivered by Prof. C. Maragliano of Genoa, Italy, on Monday evening, March 28, at the Witherspoon Building, Philadelphia, the subject being "The Specific Therapy of Tuberculosis and Vaccination against the Disease."

MAZYCK P. RAVENEL, M.D.,
Assistant Medical Director.

RECENT DEATHS.

JONATHAN HENRY ROBINSON, M.D., M.M.S.S., died in Southboro, Mass., March 11, 1904, aged seventy-three years. He was born in Surrey, N. H., in 1831, and has been a resident of Southboro since 1857. In 1888 and 1896 he was a representative in the General Court, and was at one time medical examiner of the Southboro District.

EDWARD A. WALTER, M.D., of the Borough of the Bronx, New York City, died on Feb. 27, from pneumonia. He was graduated from the University and Bellevue Hospital Medical College, New York, in 1899.

OGDEN CURTIS LUDLOW, M.D., of New York, for a number of years past recording secretary of the New York County Medical Association, died on March 2. He was graduated from the medical department of the University of the City of New York in 1883, and afterwards served as an interne of St. Luke's Hospital. Dr. Ludlow had been a reporter of various important medical society meetings for many years, and in this work had always used excellent judgment and discrimination. He was an attending physician at St. Joseph's Hospital at the time of his death. It is said that he contracted typhoid fever in Albany last January, while attending the meeting of the New York State Medical Society.

HOWARD C. RUSSELL, M.D., of the United States Marine Hospital Service, died on March 1, at Stapleton, Staten Island, N. Y., from pneumonia. He was a native of Washington, D. C., and received his academic and medical education at the University of Pennsylvania. He was appointed to the Marine Hospital Service July 1, 1897, and had been stationed at the hospital on Staten Island since 1902.

DAVID L. WALLACE, M.D., of Newark, N. J., died on March 1, at the age of forty-eight years. He was graduated from Bellevue Hospital Medical College in 1875, and for twelve years was a member of the Newark Board of Health, during a considerable portion of that time serving as its secretary.

FRANK E. BAKER, M.D., of Newark, N. J., until recently superintendent of the Newark City Hospital, died on March 1, in consequence of injuries received in a fall upon the ice on the night of Feb. 8. He was forty-eight years of age and was graduated from the College of Physicians and Surgeons, New York, in 1882.

BOOKS AND PAMPHLETS RECEIVED.

The Nutrition of the Infant. By Ralph Vincent, M.D. New York: William Wood & Co. 1904.

Social Diseases and Marriage. Social Prophylaxis. By Prince A. Morrow, A.M., M.D. New York and Philadelphia: Lea Brothers & Co. 1904.

The Practical Medicine Series of Year Books, comprising ten volumes on the Year's Progress in Medicine and Surgery. Issued monthly. Under the general editorial charge of Gustavus P. Head, M.D. Vol. III. Chicago: The Year Book Publishers. December, 1903.

A Manual of Operative Surgery. By Sir Frederick Treves, Bart., K.C.V.O., C.B., LL.D., F.R.C.S. New Edition, revised by the author and Jonathan Hutchinson, Jun., F.R.C.S. Vol. II. Illustrated. Philadelphia and New York: Lea Brothers & Co.

Diseases of the Nervous System. A Text-book for Students and Practitioners of Medicine. By H. Oppenheim, M.D. Translated and edited by Edward E. Mayer, A.M., M.D. Second American Edition. Revised and Enlarged. Illustrated. Philadelphia and London: J. B. Lippincott Co. 1904.

Fatigue. By A. Mosso, Professor of Physiology in the University of Turin. Translated by Margaret Drummond, M.A., and W. B. Drummond, M.B., C.M., F.R.C.P.E. Illustrated. New York: G. P. Putnam's Sons. London: Swan Sonnenschein & Co., Ltd. 1904.

BLOOD-PRESSURE OBSERVATIONS IN SURGICAL CASES. REPORT OF THE COMMITTEE ON RESEARCH FOR THE DIVISION OF SURGERY, HARVARD MEDICAL SCHOOL, JANUARY, 1904.

Introduction.

On Feb. 1, 1903, the following letter was sent out by the Committee on Surgical Research of the Division of Surgery of the Harvard Medical School to the surgeons of the Massachusetts General Hospital, the Boston City Hospital and the Children's Hospital.

Department of Surgery,
Harvard Medical School, Feb. 1, 1903.

Dear Sir: The recent work by Dr. Crile on surgical shock and the representation by Dr. Cushing of the importance of blood-pressure observations in surgical diagnosis and treatment have produced a widespread interest in these methods of investigation of surgical problems, and one which the Surgical Department of the Harvard Medical School desires to encourage in every way within its power.

To this end the Committee on Surgical Research has organized an investigation, in order to determine, so far as the opportunities in this community will allow, the extent to which blood-pressure observations in surgical cases may be of value from a clinical point of view.

The committee will be glad to receive the suggestions of all surgeons who may be interested in the subject, and they cordially invite your criticism of the following plan:

(1) It is proposed that a representative of the committee be appointed for each of the hospitals here concerned, the Massachusetts General, Boston City and Children's. This representative of the committee will provide the apparatus necessary for the estimation of blood pressure in clinical cases, and will give such instruction to house officers and nurses as may be needed to obtain a general use of the apparatus. He will, when desired, make observations himself and record results. He will then collect and classify the results for each hospital and assemble them for incorporation in a general report.

(2) No surgical case will be reported except so far as its bearing upon the value of blood-pressure observations is concerned, and no case will be reported without the special consent of the surgeon in charge nor without due credit being given to him in the report.

(3) It is hoped that surgeons will avail themselves of this opportunity to procure blood-pressure observations upon their patients, and that by July 1, 1903, so large a number of clinical observations may be available as to permit the publication of reports which will be of value to the profession.

(4) The co-operation of the Department of Physiology has been secured, in order that a rigid criticism may be brought to bear upon these investigations from a scientific point of view.

(5) The points which have appeared to the committee to be of most importance in this investigation are as follows:

(*a*) Does the Riva-Rocci apparatus indicate the true blood pressure with sufficient accuracy for clinical purposes?

(*b*) In what cases and under what circumstances are the errors due to the apparatus so great as to invalidate its advantageous use?

(*c*) What is the value of blood-pressure observations,
(1) As an indication for or against operation?
(2) During the course of an operation?
(3) In after-treatment of surgical cases?

It is the hope and desire of the committee that general co-operation may be secured in this investigation from all the surgeons on duty in the above-mentioned hospitals, and that a large number of observations may be recorded, in order that a just estimate of their value may be obtained.

Should this investigation, as proposed by the committee, appeal to you as worthy of your support, will you kindly sign and post the enclosed postal card before Feb. 7? A representative of the committee will then call upon you, to ascertain more particularly the extent to which you desire to avail yourself of the committee's assistance and to arrange the details of the undertaking.

Very truly yours,
Herbert L. Burrell,
Edward H. Nichols,
Robert B. Greenough,
Committee of the Surgical Department on Research Work.

The response to this letter was practically unanimous, and the committee desires here to express its thanks to the following surgeons who gave permission for the use of their wards for the purposes of this investigation:

Dr. F. G. Balch, Dr. H. H. A. Beach, Dr. J. B. Blake, Dr. W. P. Bolles, Dr. J. T. Bottomley, Dr. E. G. Brackett, Dr. G. W. W. Brewster, Dr. H. L. Burrell, Dr. A. T Cabot, Dr. Farrar Cobb, Dr. E. A. Codman, Dr. W. M. Conant, Dr. H. W. Cushing, Dr. John Dane, Dr. J. W. Elliot, Dr. W. E. Faulkner, Dr. F. B. Harrington, Dr. J. C. Hubbard, Dr. R. W. Lovett, Dr. F. B. Lund, Dr. S. J. Mixter, Dr. G. H. Monks, Dr. J. G. Mumford, Dr. J. C. Munro, Dr. C. A. Porter, Dr. C. B. Porter, Dr. Abner Post, Dr. M. H. Richardson, Dr. C. L. Scudder, Dr. J. S. Stone, Dr. Augustus Thorndike, Dr. Paul Thorndike, Dr. J. C. Warren, Dr. F. S. Watson.

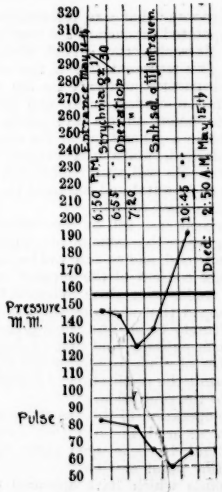
Dr. W. E. Faulkner, for the Boston City Hospital; Dr. J. S. Stone, for the Children's Hospital; and Dr. F. T. Murphy, for the Massachusetts General Hospital, were invited to exercise a general supervision of the work, and to report upon the value of the results. The Riva-Rocci sphygmomanometer was employed as introduced in his country by Dr. Harvey Cushing, and the apparatus was supplied from various sources. Five instruments were provided for use in the different hospitals. In order that the results might bear comparison, although obtained by different observers, a description of the apparatus was issued and general directions for its use were given substantially as follows:

Description of apparatus. — The apparatus consists of a dilatable rubber armlet, 5 cm. in width, encased in a covering of canvas, which can be adjusted to various sizes by means of hooks and eyes. This armlet is connected by rubber tubing to a rubber syringe-bulb with a dilatable reservoir such as is used with the thermocautery. Inserted between the armlet and the bulb, and connecting with the other tube by means of a Y-shaped joint, is another piece of tubing leading to a mercury manometer, to which

is attached a scale graded in millimeters, with the zero point at the level of the mercury. At the distal side of the manometer there is placed an escape-valve closed by a stop-cock, by means of which the pressure in the armlet can be released. The armlet is adjusted loosely to the arm just above the bend of the elbow, with the forearm flexed 30° to 45° and thus held on the same level with the body during the experiment. The armlet is dilated by forcing air from the rubber bulb until the radial pulse is obliterated by the pressure exerted on the brachial artery. At that degree of pressure which just obliterates the radial pulse the height of the column of mercury on the manometer scale is noted and regarded as the systolic blood pressure measured in millimeters of mercury. The reservoir of the manometer should be on the same level as the heart of the patient under examination, and, unless otherwise stated, all pressures are taken with the patient in the prone position. The pulse-rate is counted after the recording of the pressure. After each record the escape-valve should be opened to relieve the constriction before attempting a second reading. In palpating the radial pulse the amplitude of the beat will be noticeably increased during slight compression. With increasing compression it will gradually diminish until lost. Respiratory disturbances and physiological variations may cause some difficulty in getting an accurate reading at the first rise of the mercury column, but by maintaining the level for a few seconds or by the comparison of several readings, this is usually readily obviated. The point at which the pulse can be again palpated after it has been cut off is usually uniformly about 5 or 10 mm. lower than the point at which it disappeared.

The papers presented by Drs. Faulkner, Stone and Murphy represent the conclusions obtained in three different hospitals by different observers. No influence is exerted by the committee on the interpretation of the results, nor upon the manner of their communication. It was only stipulated that the observations be made with the same or similiar apparatus and uniform method of application. The general conclusions of each of these observers are recorded in his report, and a brief summary of the conclusions which appear to the committee to be justified by a consideration of the three series of observations is provided at the end of the communication. In this final summary an attempt is made to answer as correctly as possible the questions propounded in the original circular of the committee.

It is assumed in this communication that the Riva-Rocci sphygmomanometer registers more or less accurately the systolic blood pressure. Proof of this assumpt on, however, so far as is known to this committee, has not yet been produced. Attempts to obtain control observati ns by the use of an actual arterial manometer in man have not been recorded, and the different conditions in animals are not such as to ensure accurate results. It is the opinion of this committee that a series of such observations upon the human subject, or upon monkeys, is greatly to be desired as a test of the Riva-Rocci instrument. Until this is done, however, a clinical estimate of its value, such as is provided in the following report, is all that can be offered.



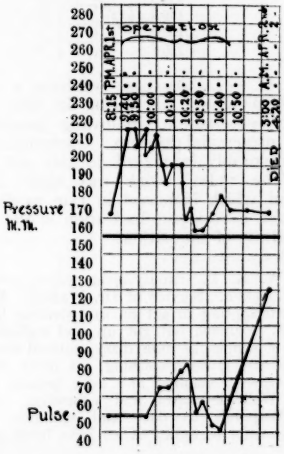
Report on Blood-Pressure Observations at the Boston City Hospital.

By William E. Faulkner, M.D.

The following cases of blood-pressure observations were made at the Boston City Hospital. The apparatus used was the modified Riva-Rocci sphygmomanometer. The conclusion of the writer is that in the general run of surgical cases blood-pressure observations do not point out dangers that could not be foreseen by observations of the patient's pulse, respiration and general condition, but that in head injuries a high blood tension may be an indication of brain compression when the pulse would not lead us to suspect such a condition.

I. J. M., compound fracture of skull. Service of Dr. Watson. Thrown from horse twenty minutes before entrance. Comatose. Responds to pain and stimulus. No paralysis. Knee jerks and plantar reflexes lively. Ankle clonus. Pupils dilated, right the more. Eyes rotated to right. Comminuted fracture left upper mid-parietal region. Brain substance visible.

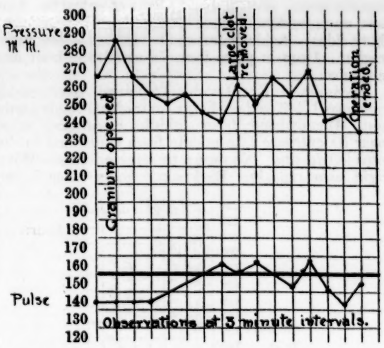
Operation. — Ether. Loose bits of bone removed. Brain found much lacerated. Considerable hemorrhage from middle meningeal region controlled by packing. Condition poor at end of operation. Died eight hours after injury.



Remarks. — In this case ator ients the drop in the pulse-rate is suggestive of rial ompression from a hemorrhage other than t e. ifrom the middle meningeal, which was co State ed by operation. With this was a conco th of P t rise in blood

pressure which may be attributed to the same cause.

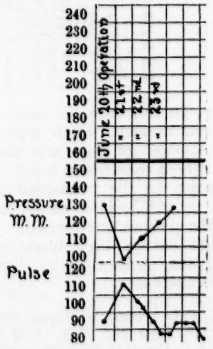
II. A. M., twenty-four years. Service of Dr. Watson. Diagnosis, fractured skull. History not obtained. Unconscious, stertorous breathing. Pupils widely dilated, not reacting to light. Laceration and ecchymosis about left eye; blood clot in nose. Pulse 48, full and regular.



Operation. — Without ether trephined on left side over middle meningeal artery. Dura bulging, not pulsating, incised. ℥ iv black clot removed. Some red oozing. Drainage. No return to consciousness or response to stimulation. Pupils remain dilated. Breathing stertorous. Died twelve hours after accident.

Remarks. — This case showed on entrance a pulse which suggested compression. The blood pressure was not remarkable. During the operation at first the pulse increased in rate and blood pressure in degree. Later both subsided to about the same point as at entrance. Following the operation the pulse took on a rapid increase in frequency until the end came, while the blood pressure remained about the same. Here the pulse told the story.

III. J. B., thirty-nine, fracture base of skull. Service of Dr. Bolles. At 9 A.M. thrown from team by collision with electric car, landing on back of head. Unable to get up, but did not lose consciousness until 1 P.M. Entered hospital 7.30 P.M. Well developed and nourished. Flushed face. Stertorous respiration. Left pupil larger than right and does not react. General spasticity of extremities, more marked on right. Knee jerks and plantar reflexes equal. Kernig's symptom left side. Small hematoma in left occipital region.

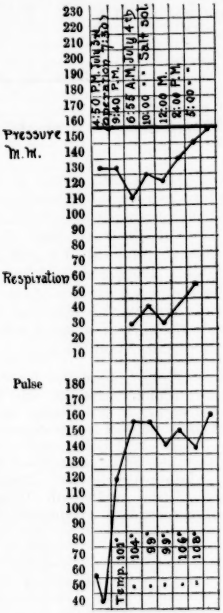


Operation. — Dr. Hubbard. Trephined over right motor area. No epidural clot. No pulsation of dura. Subdural clot extending toward base removed. No return to consciousness. Less stertorous respiration. Edema of lungs. Died twenty-four hours after accident.

Remarks. — This chart shows a high blood pressure, which can be interpreted as indicative of increased intracranial pressure due to hemorrhage, the drop in the early part of the operation being due to removal of a certain amount of this pressure. The pulse, on the other hand, is that of shock and not at all a "pressure pulse." It would seem that in this case the blood-pressure observations were of distinct value in diagnosticating a cerebral condition.

IV. J. K., ten years, depressed fracture of skull. Service of Dr. Cushing. June 20. Hit by ball one hour before entrance. In left frontal region circular depression of skull without external wound. Right pupil larger than left; both react. Involuntary defecation. Vomited once. Somewhat dull.

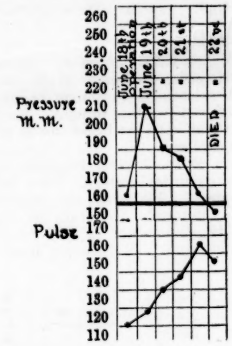
Operation. — Depression elevated. Small fragments removed. Dura found perforated. Good recovery. June 26. Entirely free from symptoms. Discharged.



Remarks. — In this case of fractured skull the lesion was apparently limited to bone and dura accompanied by slight concussion, and as one would expect neither pulse nor blood tension shows anything remarkable.

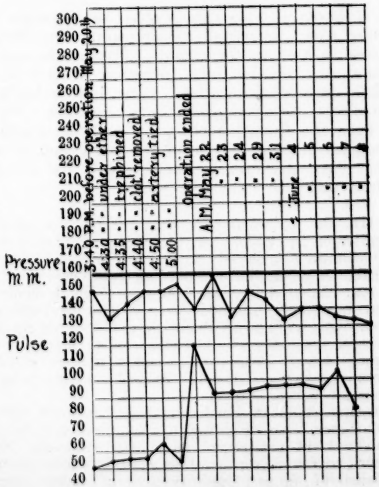
V. Unknown man. Service of Dr. Watson. Found in street. Said to have fallen on sidewalk. Unconscious. Bathed in perspiration. Pupils

equally small, not reacting to light at entrance. Later left pupil widely dilated. Slight spasticity of limbs both sides. Ankle clonus right. Abrasion left frontal region. Drop in pulse from 75 to 45 one hour after entrance.



Operation. — Dr. Lund. Trephined over middle meningeal left side. Large extradural clot turned out. Hemorrhage from middle meningeal artery near its entrance into middle fossa controlled by forceps left *in situ*. No return to consciousness. Moved right arm reflexly. Died sixty hours after injury.

Remarks. — In this case the slow pulse of 45 pointed to compression, which was verified by operation. Apparently there was also a serious basal lesion, which manifested itself by the subsequent increase in the pulse-rate and rise in temperature to 108° which came on the next day before the patient succumbed. One might have expected here a high blood pressure to correspond to the "pressure pulse," which, however, was not the case.



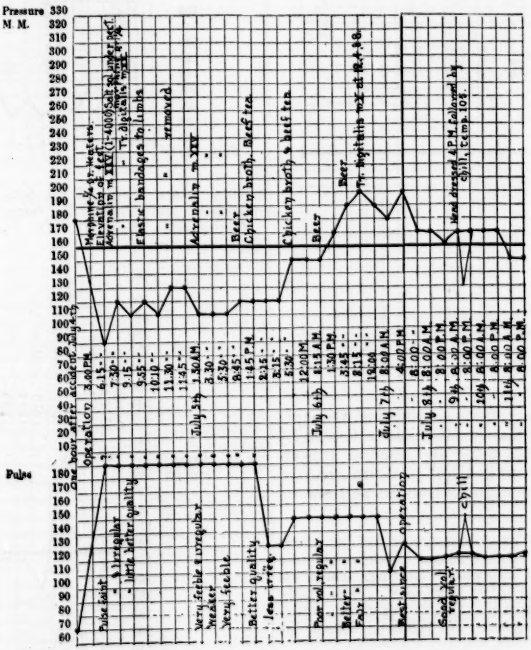
VI. J. T., sixty years, fractured skull. Service of Dr. Cushing. June 18, 1903. Fell down stairs previous night. Unconscious. Supraorbital pressure causes drawing up of right side of face and some movement of all extremities. Spasticity of left arm. Knee jerks exaggerated. Plantar reflex normal. In left parieto-occipital region scalp wound down to bone. Bleeding from left ear.

Operation. — Dr. Lund. Fissured fracture found at seat of scalp wound. Skull trephined. No extradural hemorrhage. Dura slightly pulsating opened, with discharge of 3 oz. of serum. Patient died on fifth day without return to consciousness.

Remarks. — In this case we have a patient with blood tension increasing in first twelve hours of observation, indicating possibly increased intracranial pressure. Operation seemed to act favorably in regard to this one symptom. The pulse, which was rapid at the start and which increased in rate as the case progressed, gave a true indication of the alarming condition of the patient.

VII. W. K. B., twenty-seven years, compound fracture of skull. Service of Dr. Watson. May 20. Fell on attempting to get on car, striking head on pavement. Stunned but got up and walked three-quarters of a mile; became dizzy, entered drugstore, where he was given something; sat down in park, became drowsy, vomited and later became unconscious. Well developed and nourished. Unconscious. Responds to pain and stimulus. Pupils equal and react to light. Knee jerks lively and in-

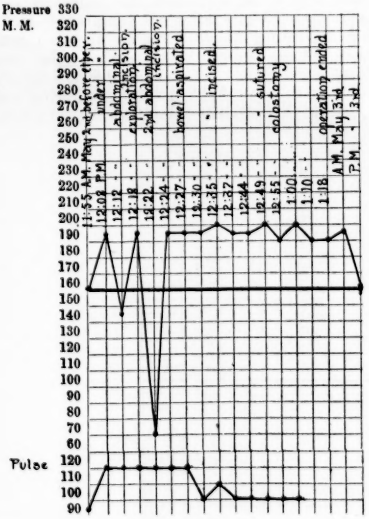
creased on right. Ankle clonus increased on right. Babinsky on right. Pulse slow and full to the tactile sense. Hematoma over left parietal region. There was a rumor that the patient was an epileptic, which afterwards proved without foundation.



Operation. — Trephined over hematoma. Fissure fracture with slight depression found. Large epidural clot removed. Hemorrhage from middle meningeal controlled by sutures. Some oozing. Dura uninjured. Wound packed. Patient rational on coming out of ether. Drowsiness on second day (May 22). Small secondary hemorrhage. Considerable clot turned out; wound packed. Wound healed by granulation. Complete recovery.

Remarks. — In this case there was a typical "pressure pulse," which disappeared on removal of clot by operative procedure. The drop in the pulse on the second day, with symptoms of drowsiness, led to suspicion of secondary hemorrhage, which was verified on inspection of wound. The blood-pressure observations were not found to be of any value in this case.

VIII. J. H., twenty-three, compound fracture of skull; compound fracture of left humerus; compound dislocation of left astragalus. Service of Dr. Watson. Team on which patient was riding smashed into by express train. Well developed and nourished. Some shock. Conscious and rational. Multiple scalp wounds. Small opening in skin at lower third of upper arm, with fracture of bone at this point. Astragalus dislocated on to dorsum of foot and skin broken through. No paralysis or abnormal reflexes.

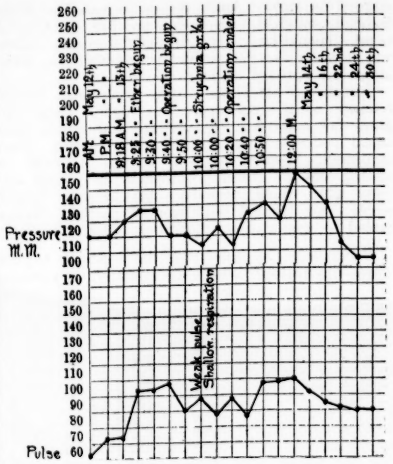


Operation. — Ether. Wounds of arm and ankle cleaned up, deformities reduced and put in plaster. Examination of head revealed fracture with slight depression in parietal region. Skull trephined, large epidural clot turned out. Oozing controlled by packing. Pulse rapid and of poor quality at end of operation.

Remarks. — At entrance the patient's pulse and blood pressure were not remarkable except that the former was slow for a man in moderate shock. Very likely brain compression from blood clot which was subsequently removed had something to do with this. Following operation the patient's condition was that of marked shock for twenty-four hours, as was evidenced by the rapid, feeble, fluttering pulse and low blood pressure. At the end of twenty-four hours the pulse dropped in rate, became better in quality and blood pressure rose. From this time on the patient's condition improved, although the pulse remained rapid for some days. An interesting thing in this case is the lack of reaction on the part of the patient to attempts at stimulation with adrenalin and digitalis, unless the drop in the patient's pulse on July 7 was in part due to the latter drug. The pulse and pressure charts are, roughly speaking, reflections of each other. Both register the patient's condition fairly well.

IX. A. G., fifty-three years, obstruction of bowel. Service of Dr. Watson. Bowels not moved for one week. Some vomiting last few days. No loss of weight. No cachexia. Abdomen slightly tender, much swollen. Tympanites. Temperature 100.

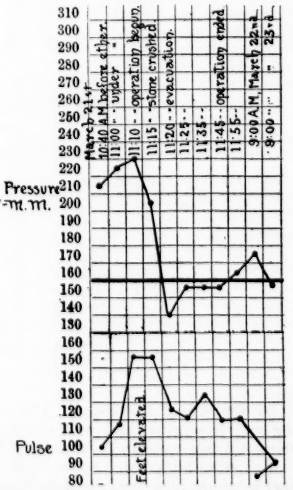
Operation. — By Dr. Watson. Abdomen explored by median incision. Transverse colon opened to let out gas. No tumor found. Left inguinal colostomy. Good recovery.



Remarks. — The patient's condition throughout the operation was excellent, as indicated by the character of his pulse and general appearance. The two drops in blood pressure occurred at points in the operation when the peritoneum was exposed.

X. C. S., fifteen years, tuberculosis of post-cecal glands. Service of Dr. Watson. Abdominal pain at times sharp and crampy. Vomiting. Diarrhea. Abatement of symptoms last three days. Pale, poorly developed and nourished. Chest negative. Abdomen lax and tympanitic. No rigidity. Tumor at McBurney's point.

Operation. — Cecum exposed. Enlarged glands alongside; some broken down. Enucleation of glands. Normal appendix removed. Drainage. Pulse feeble in character toward end of operation. Prolonged convalescence. Discharged with granulating sinus.

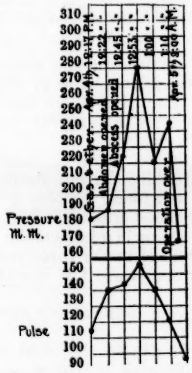


Remarks. — The condition of the patient during the operation, while not alarming, called for stimulation. This was indicated by the feeble character of the pulse and shallow respiration. The blood pressure showed no marked change. It was rather low, as one would expect in an anemic, listless subject.

XI. W. H. P., sixty years, urinary calculus. Service of Dr. Post. Symptoms of calculus for

twenty years. Several previous operations. Well developed and nourished. Some arteriosclerosis.

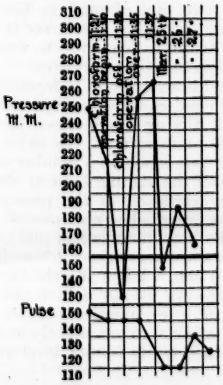
Operation. — March 21. Dr. Post. Stone crushed. Good recovery.



Remarks. — The patient's condition during the operation was excellent. The temporary increase in pulse-rate may well have been due to change in patient's position. The drop in blood pressure to the "normal" corresponds to an improvement in pulse.

XII. H. P., thirty-two years, abscess in abdominal cavity of supposed appendicular origin. Service

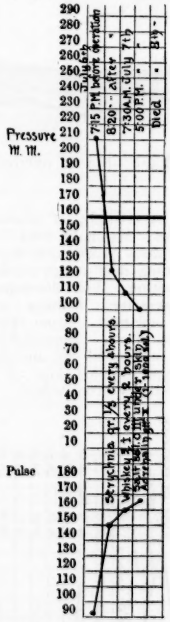
of Dr. Watson. Pain in left lower quadrant of abdomen one week. Distinct tumor. Chills.



Operation. — Dr. Watson. Abdominal cavity opened and walled off from indurated mass. The latter incised and drained. Appendix not found. Patient in poor condition at end of operation. Good recovery next day. Fecal fistula; otherwise uneventful recovery.

Remarks. — During the operation the pulse increased in rate and to the tactile sense was of poor quality. The patient's condition was such that prolonged search for the appendix seemed inadvisable. The cause of the rapid rise in the blood pressure in this case is not obvious.

XIII. M. C., forty-two years, empyema. Service of Dr. Post. Present illness followed a pneumonia. Patient running a septic temperature. Somewhat delirious. Right side of chest full of fluid. Pulse rapid, but of good quality.

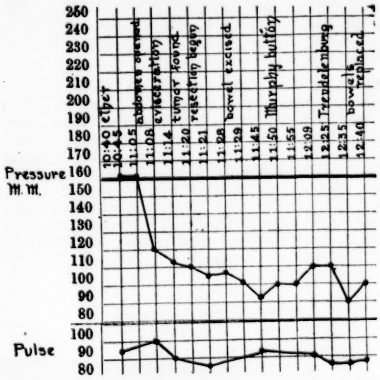


Operation. — Dr. Post. Slight chloroform narcosis. Rib resected. Pus escaped. Salt solution irrigation. Good recovery from operation. Uneventful convalescence. Discharged with slight sinus.

Remarks. — This case shows a marked drop in blood pressure under chloroform anesthesia. The pulse, though rapid, was of good quality throughout.

XIV. O. K., twenty years. Diagnosis, crushed shoulder. Shock. Service of Dr. Watson. Arm run over by steam car one hour before entrance. Well developed and nourished. Pulse slow, fair quality. Marked pallor. Compound fracture of left humerus above middle, with much laceration of soft parts.

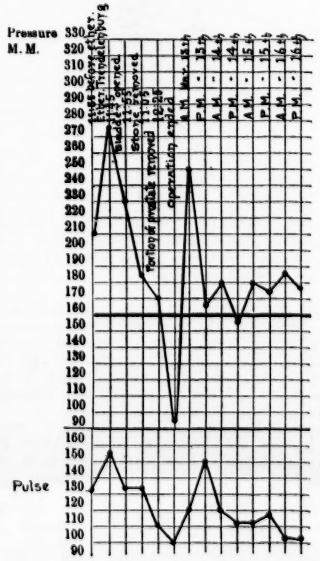
Operation. — Dr. Nichols. Under light ether disarticulation at shoulder. Very little hemorrhage. Patient stood operation badly. No reaction to stimulation. Died thirty-six hours after accident.



Remarks. — This case shows shock following severe injury, uninfluenced by stimulation. This is quite evident from the pulse curve as well as the drop in blood pressure.

XV. N. P. L., fifty-nine years, carcinoma of intestine. Service of Dr. Cushing. Crampy pains in abdomen for one year. Loss of appetite; troubled with flatus. Slight loss of weight. Fairly well developed and nourished. Skin of grayish hue. Chest negative. Abdomen somewhat distended. Visible peristalsis. Borborygmus.

Operation. — Dr. Cushing. Resection of ileum; Murphy button. "Patient in as good condition after as before operation." Died sixty hours later with onset of sharp abdominal pain and collapse.



Remarks. — This patient's condition throughout the operation was excellent, although the blood-pressure registration was low except at beginning, where the relatively high registra-

tion was very likely due to excitement in first stage of ether.

XVI. P. M., hypertrophy of prostate. Calculus. Service of Dr. Post. March 12, 1903. Three attacks of hematuria in three years with suprapubic pain. Discomfort in riding over rough road. Lately frequency of micturition. Well developed and nourished. Chest negative. Dulness over bladder region. Prostate enlarged. Urine bloody.

Operation. — Dr. Post. Suprapubic cystotomy. Removal of large amount of clot and stone 1½ inches in diameter. Hypertrophied lobe of prostate removed. Good recovery from ether.

Remarks. — The chart shows a rather variable pulse and pressure curve. The elevation of both during the early part of the operation was likely due to position of patient. The drop in pressure at the end of the operation was without significance as far as could be seen.

REPORT ON BLOOD-PRESSURE DETERMINATIONS MADE AT THE BOSTON CHILDREN'S HOSPITAL.

BY JAMES S. STONE, M.D.

THIS report deals with the results of blood-pressure determinations made at the Children's Hospital with the Riva-Rocci manometer. It deals exclusively with surgical patients, and exclusively with children.

A large number of readings were taken with a view to establishing certain absolute determinations. Age was found to play a very important part in the blood pressure. Sixty to 70 mm. is an ordinary reading in infants under six months; 80 to 90 in a child of two or three years; 100 in a child of five or six years; 110 in a child of nine or ten years.

Sex did not seem to make any material difference.

The general health of the child made a very considerable difference in the pressure. Thus, in a child sick with chronic hip disease the pressure might be 20 to 40 mm. lower than it would be expected to be in a well child of the same age. More acute diseases which profoundly affect the general health, as, for example, tubercular peritonitis, did not, as a rule, cause as marked a change in the blood pressure as did the more chronic wasting diseases. In general, the blood pressure fell in proportion to the duration of the disease and the degree of emaciation and weakness which it had produced. In the very acute diseases, such, for example, as appendicitis, where there had not been time to affect the general health, the blood pressure was not materially altered unless by other circumstances. The emaciation of the wasting diseases makes the pulse more easily felt, but at the same time exposes the brachial artery to more ready compression. These two factors tend to balance each other, although probably the latter is more important and tends to lead one to overestimate somewhat the actual fall in pressure.

Certain conditions entirely independent of the health of the child cause very wide variations in the pressure. Crying often raises the pressure from 20 to 60 or more mm. In order to verify this, readings were made on a number of children before and after the visiting hour of the parents. There was no variation in the pressure in the children whose parents had not come to see them, while in those whose mothers had just gone away, the blood pressure was raised often 40, in one case nearly 70 mm. When the children stopped crying the pressure usually fell to the previous level again within ten minutes or often less, but if the child continued to cry slightly and sob, the pressure returned to its former level very much more slowly.

Struggling, coughing, vomiting and retching likewise increase the blood pressure, so that even before etherization is begun in a patient preparatory to operation, the blood pressure may be materially altered from what might be termed normal for the individual. And during the course of an operation under light anesthesia the readings may be similarly changed. Thus the charts must be read with a knowledge of the condition of the patient while undergoing an operation as well as with a knowledge of the steps of the operation. The crying or struggling which accompanies the recovery from full anesthesia at once very materially raises the blood pressure. This change can be appreciated by the eye, independently of any observation of the pulse. It is not uncommon for an operator to become anxious because of the appearance of a child, especially if considerable blood has been lost. The ether is removed, consciousness of pain returns, the child cries, the color at once improves. These changes can be observed most readily in hare-lip or other operations on the face.

Posture likewise has a very decided influence on the blood pressure, owing to mechanical interference with respiration or with the action of the heart and to the amount of blood supplied to the head. Turning the patient on to the side during an operation may cause a fall in pressure of 10 to 25 mm. — a fall which is promptly overcome when the patient is turned on to the back again. The changes in the relative elevation of the head and trunk, such as occur in the use of the Trendelenburg table, have probably less influence on the pressure in children than in adults, but no definite observations on this matter have been made.

Before speaking of the influence of hemorrhage operative procedures and shock on the blood pressure in children, I must state that the Children's Hospital is without an ambulance service and that since these observations were begun in March I know of no child admitted in a condition of profound shock or after severe hemorrhage — conditions met with every day in the Massachusetts General and Boston City Hospitals. In the Children's Hospital, likewise, severe abdominal or cerebral operations are extremely rare, so that there are but few data from which to judge in those cases in which pressure readings promise to be of most value.

Ether causes practically always a rise in the pressure from 5 to 20 mm., averaging perhaps 10 mm. This rise occurs very promptly and lasts for some time. That it is not a result of the struggle against taking ether is, I think, wholly proved by the fact that it continues so long and that it occurs where there has been no struggle. Occasionally there is a slight fall instead of a rise, apparently due almost always to confusing circumstances.

This primary rise due to the ether was ordinarily followed by a much slower drop in pressure in cases in which the operation itself was so slight that it could exert but little influence in this particular. The operation, if one in which the shock was insignificant, seemed sometimes to cause a slight rise in pressure in addition to the rise caused by the ether, but if the operation were prolonged and the operative procedures were severe, the fall in the pressure seemed a little more marked than it would have been had the child been simply kept under ether during an operation which was prolonged but in which the operative procedures were not such as to cause shock. In ordinary operations this secondary fall did not often bring the pressure down to the starting point before etherization; it practically never brought it lower.

In some operations in which marked changes might be expected for purely mechanical reasons, the blood-pressure readings showed nothing of value. For example, in several operations for empyema the blood pressure showed no marked or definite changes. Probably the coughing and struggling under the light anesthesia counterbalanced any variations due to the changes in the lung and pleural cavity.

Ordinary abdominal operations, such, for example, as the drainage of an abscess and the removal of the appendix, showed little variation in the blood pressure. Sometimes there was a very slight rise, followed by a fall equally slight, and never to the starting point. In the other severe and prolonged operations the blood-pressure readings failed to indicate the onset of shock.

Thus, for example, during an operation for the removal of sarcomatous lymphatic glands from the pelvis, the blood pressure, which before the ether was started was 105 and which rose during the first part of the operation about 15 mm., at the end of the operation, which lasted an hour and a quarter, had not quite fallen back to the starting point. During this operation the pulse-rate seemed a more accurate guide to the child's condition than the blood pressure. Thus, at the end of three-quarters of an hour, in which glands had been dissected out from along the internal iliac vein and high up along the common iliac vessels, the lips had become pale, the color poor, the skin had become cold, the child had begun to sweat profusely, the respirations had become feeble, the pulse-rate had increased 30 beats, and yet the blood pressure had dropped but 5 mm. from what it was during the earliest part of the operation at the time of the primary rise due to the ether and still remained higher than it had been before the ether was begun.

On the other hand, during the two days following the operation the pulse-rate gradually came down, while the blood pressure also became lower, averaging 10 mm. lower than before the operation began and 20 points lower than during the last part of the operation, when the shock seemed greatest.

In one case a laparotomy was performed on a child with a pulse so poor that no reading could be made.

In another case, an operation for empyema, the radial pulse was so poor that the readings had no value whatever.

In the only head case observed, one of concus-

sion due to a fall from a third-story window, the blood pressure showed nothing.

The effect of the fracture of large bones upon the pulse-rate has often been noticed. The respiration is also often affected. The observations made during osteoclasis of the tibia and fibula and osteotomy of the femur showed that the blood pressure was also affected in varying amount. Thus, the pulse-rate immediately after the break increased from 10 to 30 beats, while the pressure, which in one case for the few seconds before the snap came and while the bone was withstanding the tremendous strain put upon it seemed to drop a little, rose from 5 to 30 mm. just after the snap. Comparing the pulse-rate and blood pressure after osteoclasis with what existed before the ether was started, we find the same conditions as exist in any simple operation, namely, a slight increase in the pulse-rate and a slight rise in the blood pressure. The slight amount of shock caused by the fracture of both legs is not indicated by any fall in the blood pressure either immediately or after the preliminary rise.

In the same way during forcible manipulations about the large joints, such as the reduction of congenital dislocation of the hip by the Lorenz method or by the Bartlett machine, which exerts tremendous traction, the blood pressure rose slightly, 5 to 10 mm., while the force was being exerted, but dropped afterward to, but not below, the point at which it had been at first.

Operations involving profound stimulation of the cutaneous nerves, as, for example, the removal of Thiersch skin grafts, caused a slight rise in the pressure, about 5 mm., but the fall in the blood pressure afterward was insignificant at first and later did not correspond with the shock incident to the prolonged operation.

In spite of the failures of the Riva-Rocci manometer to indicate the onset of shock, blood-pressure observations may be of value in preventing the unnecessary use of cardiac stimulants. The observations made at the Children's Hospital suggest that the readings indicate as much the strength of the cardiac systole as they do the general blood pressure. If this is true, the observations bear out the contention of Crile that in shock the heart, at first at all events, performs its work adequately. The Riva-Rocci readings may hasten the abandonment of cardiac stimulation when the heart is performing its work adequately, a stimulation which, if it has an effect at all, tends to fatigue the heart. The readings show nothing which ordinary clinical observation has not shown before, but because they can be recorded graphically they may have a more marked influence. Likewise, the recognition of the fact that stimulation is useless in chronic wasting diseases, such as the forms of surgical tuberculosis, may be hastened.

CONCLUSIONS AS TO THE BLOOD PRESSURE IN THE SURGICAL DISEASES OF CHILDREN.

Ether causes a rapid rise in the blood pressure as indicated by the Riva-Rocci apparatus.

This rise is followed by a very much slower fall in the pressure.

Ordinary operative procedures seem sometimes to increase the pressure slightly.

With the establishment of shock the pressure is lowered, but —

Other signs of shock, the more rapid pulse, the more feeble respiration, the cold, clammy skin, are noted earlier during operations than is a drop in blood pressure.

Conversely, patients practically pulseless at the wrist can withstand operations.

Crying, vomiting, retching, struggling or changes in position affect the blood pressure so much more than ordinary operative procedures as often to render pressure charts practically valueless, unless all these circumstances are noted.[1]

SEPTEMBER, 1903.

REPORT ON BLOOD-PRESSURE OBSERVATIONS AT THE MASSACHUSETTS GENERAL HOSPITAL. BY FRED T. MURPHY, M.D.

OBSERVATIONS were made in the wards of the Massachusetts General Hospital on 100 surgical cases. These cases were to a certain extent selected as being those which promised to give valuable and characteristic data. In these the pressure was taken for as long a time as there seemed to be any hope of a change and at four-hour intervals, or twice a day, though in a few it was possible to obtain only a daily reading. During the operations the pressure was practically watched constantly, and in conditions where sudden changes were probable the readings were taken at intervals varying from one to fifteen minutes. The observations were made in accordance with the instructions detailed in the circular and with the Riva-Rocci apparatus therein described, except that a broad (10 cm.) band with a metal armlet was used in the latter half of the cases examined. The broad and narrow bands were not used on the same case, or, if so, a control observation was made so that the different levels should not be confused. Of necessity, many of the readings were taken by the nurses and house officers, to whom I wish to express my thanks, but in all instances their observations were controlled by mine. Numerous other isolated readings were taken which were considered too scattered and irregular to warrant consideration.

The figures in the following report represent the systolic blood pressure expressed in millimeters of mercury.

There were 28 cases of head injury of varying types, of which 18 recovered and 10 died. These "head cases" are reported with considerable detail, as in injuries of this nature the blood pressure promises to give the most definite conclusions. The 18 cases which recovered will be first considered.

Two typical pressure cases with localized

[1] Many of the blood-pressure observations here reported were made by the house officers of the Children's Hospital, to whom the writer would here express his thanks.

paralysis from middle meningeal hemorrhage were seen only after operation and, as might be expected, the charts are not remarkable, one showing a level at 100 to 80 and the second running along at 120 to 140.

Five cases, all with low-frequency pulses, diagnosticated as concussion, the degree varying from a mild shake-up to complete unconsciousness, gave readings for the first twenty-four hours at levels between 85 and 180.

Five cases of fracture of the base without operation, the diagnosis resting on bleeding from the ears or sub-conjunctival hemorrhage with slow pulse and stertorous respiration and loss of consciousness, showed levels of from 110 to 190 without marked variation, except in one case, where the chart might be misleading as indicating a pressure which demanded interference (see Fig. 1). The abrupt rise of 35 mm. may be interpreted as the result of compression or reaction from the shock of injury. (Service of Dr. Elliot.)

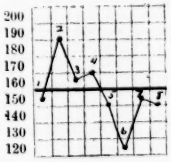


FIG. 1. — 1. In accident room late in P.M. 2. 10 P.M. 3. Midnight. 4. 3 A.M. 5. 6 A.M. 6. 11 A.M. 7 & 8. Succeeding days. Pulse 70 to 80.

Three cases of compound fracture of skull are interesting only from the low level of one, 85 to 70, which was maintained during the afternoon following operation.

A case of probable fracture of the base, which had been operated upon about one year previously for an extensive compound fracture, deserves special mention. Since operation the man had been subject to epileptic attacks, and in one of these he had fallen down stairs, striking on his head. For the first forty-eight hours after the injury he had been at home in a semi-conscious state. During the second twenty-four hours before entering he had complained of pain in the head and had vomited several times. Also it was noticed that the scar, which had formerly been depressed, was bulging. On entrance, the patient was semi-conscious, pulse about 50 and temperature 101. No paralysis. The bulging area in the frontal region pulsated synchronously with the radial, and pressure upon this area caused extreme pain. During the next forty-eight hours there was no change. On the third day a lumbar puncture was done, two test tubes of clear fluid being withdrawn, with the disappearance of the tumor and relief of pain for twelve hours. Unfortunately, no blood pressure was taken at the actual withdrawal of the fluid, but the level of the afternoon reading was not altered. On the fourth day there was a marked facial paralysis and involuntary movements of the bowels. Leeches were applied over the tumor without change to size or in the blood-pressure reading. On the fifth day the clinical condition was the same, but the blood pressure had fallen practically to the level maintained during convalescence. During the next twenty-four hours the improvement was marked. Here the blood pressure seemed to indicate a change before the usual clinical signs (see Fig. 2). (Service of Dr. Warren.)

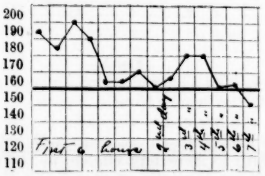

FIG. 2.

A case of tic douloureux was followed during a primary operation for the exposure of the Gasserian ganglion, and six days later during the operation for its removal. Excepting a rise to 180 before taking the anesthetic, the blood pressure did not vary over 10 mm. from the level of 150 in the first operation and 140 in the second, though the hemorrhage was severe and the manipulation of the brain at times extreme. Nor was there any change when the ganglion was divulsed. A second case of operation on the ganglion, with the exception of the rise in pressure due to the ether, held a level of 120 without greater variation than the first. (Both cases on service of Dr. Mixter.)

Of the 10 cases which died, 3 fractures of the base dying within the first twenty-four hours kept a level of 130, 150 and 190 respectively until the moribund drop. This final decline in the blood pressure was constant in all types of cases, the time of its onset varying between wide extremes and with the degree of the general collapse. The temperature, pulse or general appearance of all these cases indicated a hopeless condition.

A case of concussion, so called from negative symptoms, showed a four-hourly chart with a rise from 80 to 110 during the first sixteen hours, though the temperature had gone from 101.8 to 107.

A hopeless fracture of the skull gave a pressure after the operation of 120, with a pulse-rate of 140, and in a case of intracranial hemorrhage on both sides, as proved at autopsy, which had been operated upon with removal of the clot only from one side, the blood pressure was negative, as indicative of local or general condition.

Another case classed as concussion gave the following chart, which had been reduced from a four-hourly to a 2 i. d. Lumbar puncture, with withdrawal of two test tubes of fluid, caused no permanent or immediate change in the pressure. The pulse went to 140 on the eighth day and the

temperature to 104.5, forty-eight hours before death. Died in the afternoon following the last record (see Fig. 3). (Service of Dr. Richardson.)

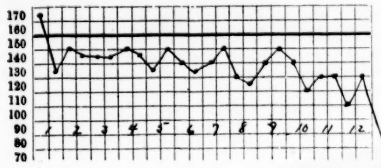

FIG. 3.

The chart of a case in which a blasting accident blew off the whole frontal region, with laceration of the brain and the face, is given because of the low pressure on entrance, on April 6, the failure to show any change at the section of the optic nerve in the operation for the enucleation of the eye and the clearing up of the lacerations and the marked rise which antedated by three days any suggestive change in the pulse or temperature. The nature of the wound was such that an infection was inevitable and at autopsy a pneumococcus meningitis was found. Sepsis rather than compression would seem to have been the cause of the abrupt rise in the blood pressure (see Fig. 4). (Service of Dr. Richardson.)

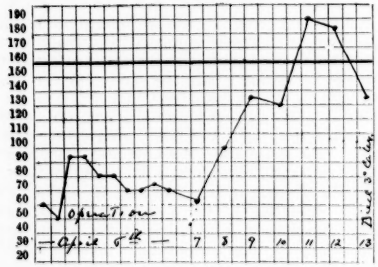

FIG. 4.

A second case of compound fracture of the skull, which from clinical signs died of meningitis, is included for comparison with the preceding. Here the temperature shot to 105 on the 25th and the pulse began its final rise on the 28th. Irregular four-hour chart reduced to a 2 i. d. (see Fig. 5). (Service of Dr. Elliot.)

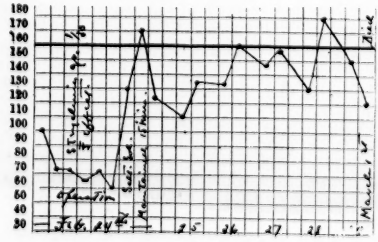

FIG. 5.

The final head case, a fracture of the base with laceration of the brain, as shown at autopsy, gave the following chart, which was reduced from a four-hourly to a 2 i. d. At operation the dura was very tense and cerebrospinal fluid escaped as if under great pressure, but, as can be seen, excluding the elevation at the beginning of the operation, which was probably due to the ether, there was no marked change, the afternoon reading being 10 mm. higher than the morning. On the 28th the temperature went to 105, where it remained and the pulse shot up on the 27th, but until the final drop on the 29th the pressure record is not remarkable (see Fig. 6). (Service of Dr. Elliot.)

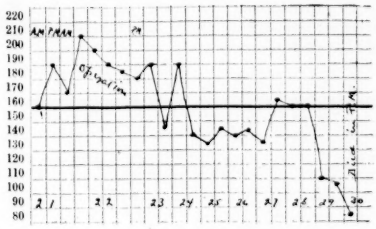

FIG. 6.

The negative charts of the 18 cases which recovered may be considered as confirmatory of the other clinical signs. The failure of the 10 fatal cases to show more diagrammatically any increase in the intracranial pressure or to indicate more clearly the general condition emphasizes the influence of diverse factors in such injuries. That cerebral compression of sufficient degree does, up to a certain point, increase the tension of the pulse, is an accepted fact based on clinical experience. The Riva-Rocci or other apparatus simply records this graphically. The influence of shock, hemorrhage and dyspnea is not, however, to be disregarded. Only by considering their influence on the blood pressure, together with the previous as well as the present general condition of each individual case, does it seem that a safe balance could be struck. The blood pressure here, perhaps, more than in any other type of injury, is the sum total of such varying influences that it must fail to be typical in many instances. Judged from this series, the blood pressures as isolated data are disappointing. They failed to assist materially in determining the surgical condition. No level or curve, excepting the final decline, was constant. The definite, graphic record, however, of a quantity which is accepted as being influenced by variations in the degree of intracranial compression should give valuable data in certain cases when combined with the other symptoms.

Routine cases as seen in the accident room

and wards will be considered under one general group.

The extremes, as taken on accident-room cases, were 65 and 235. The former, a case of railroad accident with a compound fracture of both bones of the right arm and leg, a fracture of the ribs and questionable fracture of the pelvis, made a good recovery. The blood pressure confirmed the clinical diagnosis of extreme shock. The latter, an acute retention, was relieved and walked out. This high tension doubtless went with the arteriosclerosis and probable kidney complication.

Shock in varying degrees is illustrated by the following cases: A superficial and not extensive burn entered with a pressure of 235, which within an hour dropped to 190 to 200, where it remained. A fatal general burn gave, on an half-hourly chart, a pressure of 120 to 105 during the first day, with two drops to 90, which were held for one hour. In the night the radial pulse was too weak to give a reading, but the next day a pressure of about 70 existed. Again at night the pulse was lost and the patient died the next day. Here strychnia, atropin and subcutaneous infusion of salt solution caused no rise. (Service of Dr. Beach.) A case of fracture of the thigh, color good, pulse at 70, had a pressure of 170; another fracture of the thigh, mild shock, pulse of 100, had a pressure of 190; a compound fracture of the thigh, general condition poor, dying that afternoon, gave a pulse of 140 and a pressure of 165; a bad crush of the shoulder with ultimate recovery, but too weak to allow immediate operation, showed the pulse at 110 and pressure 110; a crush of arm and leg, hopeless, dying in a few hours, had a pulse of 110 and pressure of 125, and so on.

Judged by the immediate reaction and the subsequent course with varying degrees of shock, the blood pressure generally confirmed the other clinical signs, but in many instances the height of the level maintained was misleading. Here again the moribund fall appeared to be the one constant feature. The general appearance, respiration and pulse-rate gave in all instances a better idea of the condition than could be obtained by judging from the blood-pressure readings.

The acute abdominal cases observed before operation were only a few, but there was no suggestive level, rise or fall in the blood pressure. No case was observed before and during the onset of acute abdominal infection.

Anesthesia is commonly given at the Massachusetts General Hospital as follows: Nitrous oxide gas is administered with a Bennett inhaler and ether is substituted when the gas anesthesia is complete. The pressure under these conditions is quite typically shown in the following chart; that is, a preliminary rise with the gas, then a fall of 10 to 20, followed by a sudden elevation of 30 to 40 at the first of the pure ether, and then a gradual drop to a level 10 to 20 above the original base line. While this scheme held in general, exceptional elevations of as much as 100 mm. were noted under the early ether (see Fig. 7). (Service of Dr. C. B. Porter.)

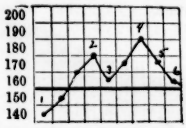

Fig. 7. — 1. Before starting gas. 2. Straining under gas. 3. Under gas. 4. Straining under ether. 5. Easy breathing. 6. Ready for the table.

Charts of different operations are given to illustrate the effect as shown by the blood pressures.

Operations of the type clinically supposed to produce no shock, such as interval appendectomy, hernia, etc., may be exemplified by a chart of simple drainage of the gall bladder (see Fig. 8). (Service of Dr. Beach.)

Fig. 8. — 1. Partially etherized. 2. Beginning operation. 3. Opening belly. 4. Digital exploration. 5. Walling off. 6. Aspirating gall bladder. 7. Probing for stones. 8 & 9. Tying in Mixter tube. 10. Moving gauze. 11. Manipulation of the common duct. 12. End of operation.

In a case of rupture of the spleen in which there was, of necessity, rough manipulation of the intestines and parietes and where a counter-opening was made in the loin, the variations are not striking (see Fig. 9). (Service of Dr. Elliot.)

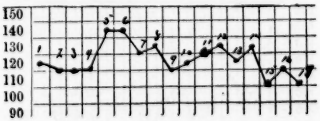

Fig. 9. — 1. Belly wall. 2. Opening belly. 3. Handling intestines. 4. Salt solution washout. 5. Walling off. 6. Salt solution washout. 7 & 8. Rough handling of intestines. 9 & 10. Packing on spleen. 11, 12 & 13. Sewing up. 14. Opening in loin. 15. Packing on spleen. 16. Sewing up. 17. End of operation. Pulse 80 to 120.

The following chart of a case of high amputa-

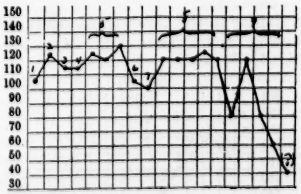

Fig. 10. — 1. Before operation. 2. Primary ether. 3. Circular incision down to bone. 4. Sawing bone. 5. Tying off and applying dressing. 6. End of operation. 7. In ward immediately after operation. 8. Salt solution intravenously, 1½ pints, level maintained eleven minutes. 9. Following at five-minute intervals. Pulse 90 to 140. Patient died a few minutes after the last record.

tion of the arm, which was all but in extremis from sepsis, is remarkable only from the graphic fall in the blood pressure when the patient was dying (see Fig. 10). (Service of Dr. Warren.)

An omentopexy gave the following record (see Fig. 11): (Service of Dr. Conant.)

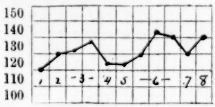

FIG. 11. — 1. Belly wall. 2. Opening belly. 3. Exploration. 4. Rubbing peritoneum. 5. Rubbing liver. 6. Sewing up omentum. 7. Sewing up. 8. End of operation. Pulse 110 to 100.

A fatal strangulated hernia in an old man who seemed to be in a very bad condition, color poor, pulse 120 and respiration labored, gave this chart (see Fig. 12): (Service of Dr. Beach.)

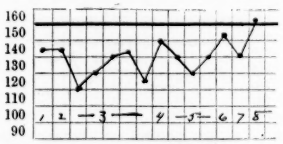

FIG. 12. — 1. Sac opened. 2. Manipulation of bowels. 3. Resecting gut and putting in Murphy button. 4. Two minutes after atropin gr. $\frac{1}{75}$ subcutaneously. 5. Sewing up mesentery and closing abdominal wall. 6. Straining under light ether. 7. End of operation. 8. One hour later in ward. Pulse 95 to 120.

A general peritonitis in a child of seven, in an extremely bad condition, gave this record (see Fig. 13): (Service of Dr. Warren.)

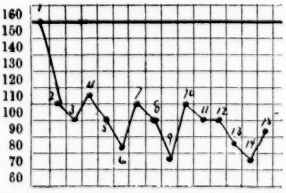

FIG. 13. — 1. In accident room. 2. Just on table. 3. Belly wall. 4. Straining under light ether. 5. Exploration. 6. Salt solution washout. 7 & 8. Removing appendix. 9. Washout. 10. Three minutes after strychnia gr. $\frac{1}{30}$ subcutaneously. 11 & 12. Wicks. 13 & 14. Sewing up. 15. Close of operation. Pulse 140 to uncountable.

A case similar to the above in an adult showed the following chart (see Fig. 14): (Service of Dr. C. B. Porter.)

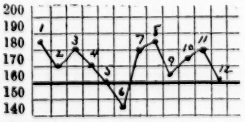

FIG. 14. — 1. Under ether. 2. Belly wall. 3. Peritoneum opened. 4. Exploration. 5. Exploration of pelvis. 6. Salt solution washout. 7 & 8. Wicks. 9. Further exploration. 10. Sewing up. 11. End of operation. 12. In ward one hour later. Pulse 106 to 120.

A case of extra-uterine pregnancy with rupture and intraperitoneal hemorrhage reacted in this diagrammatic manner (see Fig. 15): (Service of Dr. Warren.)

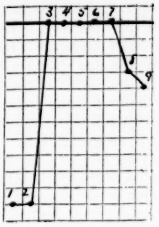

FIG. 15. — 1. Opening belly. 2. Straining under ether. 3. After one pint salt solution intravenously. 4. Right tube removed; salt solution up to 1½ pints. 5. Salt solution up to 2 pints. 6. Intestines washed out of belly. 7. Sewing up. 8. End of operation. 9. Thirty minutes after operation. Pulse of 130 to 150.

The blood-pressure curve during the operations did not give so accurate an idea of the general condition as the routine clinical signs, — pulse, respiration and general appearance. Changes were noted earlier by judging from the composite picture, and as substantiated by subsequent course the blood pressure alone might be most misleading. This was true both as indicating a good as well as a poor condition.

Operations on the pelvis, necessitating the Trendelenburg position with its changing levels, so confused the readings that they were useless.

Isolated cases of possible interest were: An adrenal tumor with metastasis in the brain, with sufficient pressure to press forward through the vault, ran along at 105 to 115; a kidney decapsulation ten days after operation showed a level at about 140; a case of nephrectomy, which later died, gave some months after the operation a pulse of 80 and a pressure of 210 to 280; two cases of tetanus had, as might be expected, high pressures of from 210 to 240; a case of septicemia, which was running a temperature of from 100 to 107, and which was being treated by intravenous injections of formalin, ran an irregular daily chart of from 90 to 120 until the final drop, the temperature seeming to have no close relation to the pressure; a fatal case of hemorrhagic jaundice held a level of 140 to 120, with a pulse at 150 to 160 without noticeable change from strychnia, atropin or gelatin subcutaneously; a polyp of the uterus, which had caused such hemorrhage as to reduce the hemoglobin to 40% gave a pressure of 205 and a pulse of 125. This last case might be interpreted either as showing the pulse to be much stronger than was estimated by digital compression or as giving a high blood pressure which was due to the size of the arm and other conditions, and which did not estimate accurately the pulse force. The case went on to final recovery, but, on the day when the pressure of 205 was recorded, she was in such poor condition that the prognosis was decidedly doubtful. Dr. Torbert very kindly took observations for me on six cases of eclampsia at

the Boston Lying-In Hospital. During the convulsions the blood pressure ran along between 225 and 240. After the acute stage the pressure fell gradually to levels varying between 140 and 160, the changes taking place in accordance with the clinical symptoms.

The chart of a moribund septic case, in which 350 cc. of adrenalin — 1–10,000 — was used, is also of interest (see Fig. 16). (Service of Dr. Elliot.)

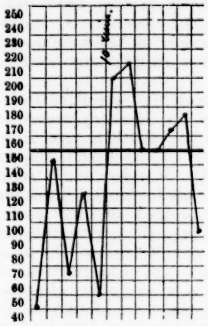

Fig. 16. — Five-minute intervals except where marked. Died thirty minutes after last reading. Pulse 150 to 160.

The peritonitis and other cases after operation showed nothing remarkable. The levels ran along without marked variation at 90 to 160. Changes in the condition were noted earlier and with greater accuracy by the usual clinical observations than from the blood pressure. The moribund fall was the one change which was universally found. In no case did the blood pressure give information regarding the patient's surgical condition which was not obtainable from the pulse, respiration, temperature and general appearance.

Strychnia and atropin subcutaneously did at times, as seen in some of the foregoing charts, cause a slight change in the level of the blood pressure, but, as a rule, in sick cases no marked variation in the curve was noted.

Salt solution in favorable cases, as in the extra-uterine before mentioned, raised the level materially, and this gain was usually held for about 25 or 30 minutes. In some instances, however, the infusion failed to check the fall, or, if there was a rise in blood pressure, it was maintained only momentarily. Where so large an amount as two pints of salt solution was given intravenously, the maximum elevation of the blood pressure was reached during the first pint.

The following chart will serve to illustrate the reaction after intravenous salt solution in favorable cases (see Fig. 17). (Service of Dr. A. T. Cabot.)

These statements are based on the results of blood-pressure observations which were made on 100 surgical cases, including 28 cases of head injury, and may be summarized as follows:

The Riva-Rocci manometer was employed in every case. A 10 cm. armlet and metal cuff

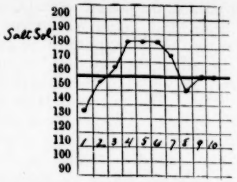

Fig. 17. — 1. Ordinary level. 2. Preparing arm. 3. One half pint. 4. One pint. 5. One and three-fourths pints. 6. Two pints. 7. Two minutes after infusion, level maintained twenty-five minutes. 8. Thirty-five minutes after infusion. 9. Forty-five minutes after infusion. 10. One hour after infusion.

was used in approximately one-half of these observations, and gave more satisfactory results than did the narrow armlet.

The blood pressure in the majority of cases confirmed the estimate of the clinical condition of the patient obtained from the pulse, temperature and other physical signs.

Deductions regarding the clinical condition drawn from the blood-pressure observations did not agree in a certain number of instances with the conclusions based upon the results of the routine clinical observations. The subsequent course of the cases proved the blood-pressure readings to have been misleading.

The blood-pressure observations did not in any case show facts that proved to be of importance in determining the diagnosis, treatment or prognosis which could not be obtained in the routine methods of clinical examination.

The effect of the common subcutaneous stimulants was not marked.

Normal salt solution, as a rule, raised the blood pressure, the maximum rise being reached with the administration of the first pint. The increased pressure was maintained for a variable period, usually about thirty minutes.

Cases of head injury, while not always typical and uniform in the reaction, as shown by the blood-pressure readings, seem to offer a field in which blood-pressure observations may prove to be of material assistance to the observer.

Summary of the Results of the Investigation. By the Committee on Surgical Research.

The questions which appeared to the committee to be worthy of investigation were as follows:

(1) Does the Riva-Rocci apparatus indicate the true blood pressure with sufficient accuracy for clinical purposes?

(2) In what cases and under what circumstances are the errors due to the apparatus so great as to invalidate its advantageous use?

(3) What is the value of blood-pressure observations —

(*a*) As an indication for or against operation?

(*b*) During the course of an operation?

(*c*) In after-treatment of surgical cases?

Question (1) — Does the Riva-Rocci apparatus

indicate the true blood pressure with sufficient accuracy for clinical purposes? — and *Question* (2) — In what cases and under what circumstances are the errors due to the apparatus so great as to invalidate its advantageous use? — cannot be authoritatively answered by the data in the hands of the committee. In the report from each hospital a certain number of facts appear which have a bearing upon these questions. A special series of observations was also made by Dr. F. T. Murphy with different forms of apparatus, and under normal as well as under pathological conditions. The results of these observations, which were made by Dr. Murphy at the request of the committee, are embodied in this summary. A laboratory test of the Riva-Rocci apparatus to determine the extent of its errors and imperfections was not contemplated by the committee, but rather a test of its practical value at the bedside. So far as the observations of Drs. Faulkner, Stone and Murphy go, the result of this clinical test is as follows:

It is apparent that the blood pressure is not recorded accurately under certain well-defined conditions. Arteriosclerosis and excessive development of fatty subcutaneous tissue and of muscle appear to cause an overestimate of the true blood pressure by the use of the Riva-Rocci narrow band apparatus. Repeated observations on the same normal individual, and with the same technique of application, gave practically constant readings. Variations were found with different observers under the above conditions, but with those who were accustomed to taking the pulse the error was so slight as to be negligible.

The rapid variation of the force of the heart beat in cases of dyspnea caused difficulty in the accurate estimate of the exact pressure necessary to ooliterate the pulse. Maintenance of the pressure in the armlet at a point sufficient to obliterate all but an occasional pulse-wave of more than average force appeared to give the most accurate results under these conditions.

Emotional and psychic causes produced extreme fluctuations in the blood-pressure readings. In children greater variations were found to be produced by these conditions than by grave alterations in the physical condition. This observation, however, does not appear to be due to the apparatus in any way, but merely interferes with accurate deductions being made from a given observation.

Change of posture appears to alter the peripheral blood pressure to a marked degree. Four normal individuals were observed by Dr. Murphy both in the prone position and in extreme Trendelenburg position. The results were as follows:

No.	*Prone.*	*Trendelenburg.*
1	189	155
2	143	145
3	163	150
4	155	180

It will be noticed that the alteration in the blood pressure is not constant either in direction or degree. The pulse in all four cases was lowered four to six beats a minute by the change to the Trendelenburg position.

No difference was apparent between the blood pressure in the two brachials in a case of hemiplegia.

Observations were made by Dr. Murphy upon a number of normal individuals and the majority fell within the limits of 120 to 160 mm. of mercury which was given by Gumprecht [1] as the result of a series of observations on normal individuals. Many apparently normal cases, however, gave readings beyond these limits, and estimates of the blood pressure as low as 100 and as high as 200 mm. were occasionally noted in normal individuals.

The modification of the Riva-Rocci apparatus introduced by von Recklinghausen,[2] in which an armlet of 15 cm. width is used in place of the 5 cm. armlet of the original apparatus, was adopted by Dr. Murphy, and a series of observations was made by him with this form of apparatus, which seemed to give lower and more accurate readings than with the narrow band.

A number of different widths of armlet were then obtained and comparative observations were made in a large number of cases. An armlet of 10 cm. width was found to give readings of practically the same degree as those which were wider and more cumbersome. The metal cuff, outside of the rubber armlet, as recommended by von Recklinghausen, was found to exert far less influence than the width of the armlet in every case.

An article by W. B. Stanton, *University of Pennsylvania Medical Bulletin*, 1903, Vol. xv, gives an excellent description of the comparative merits of broad and narrow armlets with the Riva-Rocci apparatus. Dr. Stanton recommends for ordinary use an armlet 3¼ inches in width, with canvas or leather cuff.

A series of observations made with the 5 cm. and 10 cm. armlets was as follows:

Circumference of Arm.	*Reading with 5 cm. Band.*	*Reading with 10 cm. Band.*	*Circumference of Thigh.*	*Reading with 5 cm. Band.*	*Reading with 10 cm. Band.*
21.5 cm.	125	105	35.5 cm.	205	120
23. ,,	175	165	33. ,,	220	175
19. ,,	123	115	29. ,,	235	115
20. ,,	118	100	33. ,,	235	125
20. ,,	135	115	32.5 ,,	190	115

It is to be noted that the blood-pressure readings are, as a rule, lower with the broad armlet by from 8 to 20 mm. and that the individual variation is diminished. That the influence of the soft parts is, to a certain extent, obviated by the use of the broader armlet may be deduced from a comparison of the pressures obtained in the brachial and in the femoral arteries in this series of observations.

When a manometer has been directly connected with an artery in man, as in the instances related by Albert and by Faivre (Masing [3]), pressures of 100 to 160 mm. have been recorded. The use of the 10 cm. armlet gives results which

[1] Gumprecht: Munchener Med. Woch., No. 40, 1899.
[2] von Recklinghausen: Archiv. f. Exper. Pathol. und Pharmac., Bd. 46, p. 78.
[3] Masing: Deut. Archiv. f. klin. Med., Bd. 74, Hft. 3 and 4.

more closely approach these actual experiments. The broad armlet, moreover, gives more definite compression of the artery, and the point at which pulsation ceases is more readily determined. For a discussion upon the physiology of this matter the reader is referred to papers by von Recklinghausen [4] and by Masing.[5] In actual clinical work these theoretical considerations appear to be justified by the results.

To sum up briefly:

(1) The inaccurate readings obtained in cases of arteriosclerosis and excessive muscular development are partially obviated by the use of a 10 cm. armlet with the Riva-Rocci apparatus.

(2) The presence of dyspnea causes inaccuracy in the blood-pressure determinations with either a broader or narrow band.

(3) Change of posture invalidates the readings obtained with either form of apparatus.

(4) Emotional individuals and children show fluctuations of the blood pressure out of all relation to the actual condition of the patient.

(5) Under other circumstances than those above recorded, the accuracy of the determinations with the Riva-Rocci apparatus appears to be sufficient for clinical purposes.

Question (3) — What is the value of blood-pressure observations (*a*) as an indication for or against operation? It is in this field that the value of the systematic determination of the blood pressure appears to the committee to be of the greatest promise. It is to be noted, however, that with the present knowledge which we have of the conditions which cause changes in the blood pressure, deductions can be made only when the conditions of the individual case are thoroughly understood. In emotional individuals and children, in cases of arteriosclerosis and of excessive muscular development and in patients suffering with dyspnea, the readings of the Riva-Rocci manometer, for reasons above recorded, are inaccurate. In injuries and diseases of the head, blood-pressure readings have promised to be of the greatest significance. The part played by the blood pressure in the symptoms of cerebral compression has been worked out by Cushing.[5] It is generally accepted that increased cerebral pressure causes an elevation of the blood pressure to overcome the anemia of the medullary centers. For this reason, increase of the blood pressure, as determined by the Riva-Rocci instrument, would, it was hoped, provide a definite indication for interference in cerebral injuries and diseases. In injuries of the head, however, the presence of shock to a greater or lesser degree must be considered, and its effects upon the blood pressure in an individual case eliminated before deductions of value can be made. It is owing to this fact especially, so far as the committee is able to judge, that the observations reported on cases of head injury have given so little general satisfaction.

In cases of surgical shock the low blood-pressure observations serve, as a rule, only to confirm a diagnosis already made by the physical examination of the patient. It can be stated that a low blood pressure is to be expected in the presence of surgical shock. The actual estimate of the patient's condition and the prognosis as to life or the ability to withstand surgical interference were, as a rule, more accurately estimated by the other methods of physical examination.

In a few cases the evidence, as obtained from the blood-pressure observations, appeared even to be misleading. In hemorrhage the condition of the patient, as estimated by the pulse, respiration, temperature and general appearance, seemed to be more valuable than the blood-pressure observations. In acute abdominal conditions and in sepsis the number of observations was comparatively few, but no data of importance were obtained.

To sum up the entire matter it may be stated that graphic determination of the blood pressure by means of the Riva-Rocci instrument may be judged as an indication for or against operation only after a consideration of all of the conditions which enter into a determination of the blood pressure in the individual case. It cannot be said that a blood-pressure reading of a given degree is indicative of a given condition, but like the symptom of leucocytosis an estimate of the blood pressure may help to determine for or against operation in an individual case when taken into consideration with all of the other symptoms. The cases in which blood-pressure determinations appear to offer the greatest promise are those in which the element of shock and the element of cerebral compression are present.

Question (3) — (*b*) During the course of an operation? A change in the position of the patient is liable to cause a change in the blood-pressure reading so great as to negative its value. During the early stages of anesthesia by gas or ether, elevation of the blood pressure is to be expected. Recovery from anesthesia may also cause an elevation. The results of salt solution infusion and of subcutaneous stimulation may be determined in some cases by means of the apparatus. As a general rule, however, the condition of the patient, as judged by the ordinary physical signs, gave more satisfactory data on which to base an estimate of his physical condition than the blood-pressure reading taken by itself. The value of blood-pressure observations during the course of an operation was not apparent as a result of this series of observations.

Question (3) — (*c*) In after-treatment of surgical cases? In the after-treatment of surgical cases the number of observations made was comparatively few. The results of stimulation have been recorded above. At a period shortly before death a marked and rapid drop in the blood pressure was repeatedly observed. This drop in the blood pressure occurred with equal regularity in cases of shock, fractures of the base, general peritonitis and sepsis. This " moribund drop " made its appearance at varying intervals before death ensued, but in no case was there any doubt

[4] von Recklinghausen: Op. cit.
[5] Cushing: Kocher's Hirnerschutterung, etc. Nothnagel's Spec. Path. and Ther., 1901, Bd. 9, Theil 3, Abt. 2, p. 186.

from the general physical condition of the patient at this time that death was imminent. When recovery ensued after operations, except for the results of stimulation above recorded, no data of value in the after-treatment of the cases were obtained.

To summarize the results of this series of observations it may be said that the value of the Riva-Rocci apparatus in determining the blood pressure in surgical patients is limited to a comparatively small number of cases. The conditions of cerebral compression and of surgical shock produce the most marked and definite alterations in the blood pressure. When these conditions are present and other confusing causes of alteration in the blood pressure are eliminated, the value of the blood-pressure determinations, as an indication for or against operation, is increased. Under other circumstances the value of these observations is at present not apparent. The adoption of blood-pressure observations in surgical patients does not at present appear to be necessary as a routine measure.[6]

Medical Progress.

REPORT ON OBSTETRICS.

BY FRANK A. HIGGINS, M.D., BOSTON.

(Concluded from No. 9, p. 244.)

THE JUSTIFIABILITY OF PERFORATION OF THE LIVING CHILD.

HOFFMEIER [10] says that this question cannot be considered as entirely settled, even with the great improvement in the results of Cesarean and symphysiotomy operations, but that it has become necessary to reconsider the indications for the operation. Some men are of the opinion that a recognition of the child's right to live gives the obstetrician alone the right to decide by what means the woman shall be delivered, whether by symphysiotomy or by Cesarean section. He speaks of the difficulty of arriving at correct measurements of the pelvis in the living subject, and on the importance of estimating the size and hardness of the fetal skull, and its proportion to the size of the pelvis. In determining the justifiability of perforation of the living child at term, he believes that this cannot be decided by statistics alone, but only by considering the principles which are derived from an experience of individual cases.

In the first place, the external conditions are of importance; in women with marked pelvic contraction in whom the child is still of full vitality, if the patient can be placed in a well-appointed hospital or, generally speaking, under the most favorable hygienic conditions, it is not only the right but the duty of the medical attendant to deliver by Cesarean section in the interests of the child; but in cases where the contraction is somewhat less marked, and where the other conditions are not present, the chances for the mother are much more doubtful, and it is impossible to recommend to her to submit to the increased risk of Cesarean section as compared with perforation of the living child.

But even in the obstetric clinic, cases occasionally occur in which the only proper treatment consists in perforation of the living child, at least for those physicians whose practice it is. In the medium degrees of pelvic contraction, especially in primiparæ, it is best to wait and watch the action of the natural forces. In these cases it is difficult to know how long to wait, and in primiparæ the time for turning is sometimes over while yet delivery by the forceps is very dangerous to mother and child. Here symphysiotomy or Cesarean section entail too great a risk for the mother, and there only remains perforation. Neither the law nor our own conscience will justify us in performing symphysiotomy or Cesarean section in any case against the will or without the consent of the patient. The question is no doubt simplified when during a long, expectant treatment of labor the child dies, but it is clear that when the condition of the mother urgently calls for delivery it is immaterial whether the child dies spontaneously or as a result of perforation.

He concludes that even in the present advanced state of surgical midwifery, perforation of the living child in certain cases is still the most favorable method of delivery, both in private practice and in lying-in hospitals, and that we are not justified in replacing it by symphysiotomy or Cesarean section merely because of ethical and theoretical considerations of the child's right to live. It is, however, to be desired that an exact and correct application of these two operations may reduce the necessity for perforation of the living child to a minimum, at least in lying-in hospitals.

ECLAMPSIA.

Dr. Lapthorn Smith, [11] in reply to the question as to what is the best treatment of eclampsia, says one that will in the quickest possible manner and with the least possible danger put an end to the fearful vasomotor spasm and allow the blood to rush into the brain and kidneys so that the woman may regain consciousness and so that her kidneys may at once begin to eliminate the toxin which causes the spasm.

[6] The experimental and clinical research entitled "Blood Pressure in Surgery," by George W. Crile (published by Lippincott, Philadelphia and London, 1903), has come into the hands of the committee only after the completion of this report. Dr. Crile has made many observations upon the blood pressure in surgical cases, and his reports are of great interest. It is to be noted that Dr. Crile found somewhat the same conflicting elements in the blood-pressure observations in individual cases which have been noted in this series of reports. In cases of head injury or operation, Dr. Crile found the element of shock to modify the expected elevation when intra-cranial pressure was increased.

The conclusions drawn by Dr. Crile are as follows: "During important operations and in the after-care of certain cases, blood-pressure determinations were frequently of vital importance. . . . The blood pressure of individuals varies within a wide range; for a number of causes blood pressure in the same individual varies greatly. It is particularly difficult to eliminate the psychical factor. It is frequently difficult to interpret the blood-pressure readings when their indications are most needed. The methods of determining the pressure thus far devised are only relatively accurate. In surgical practice blood-pressure determinations have added a new resource of a fair amount of practical value. The observations during surgical operations correspond very closely with those previously published as observed in experiments on animals."

[10] Journ. of Obstet. & Gyn. of the Brit. Emp., Vol. iii, No. 5, 1903. Zeit. fur Geburts u. Gyn., Bd. 48, H. 2.

[11] Annals of Gyn. and Ped., January, 1904, p. 18.

He administers first a large dose of morphine, and follows it shortly by tincture of veratrum viride hypodermically. He says this method has been used in over forty cases without a death in the largest lying-in hospital in Canada, and since its administration has been instituted no death from eclampsia has occurred in the institution. He first administers morphine subcutaneously, a half or three-quarters of a grain, followed in five minutes by a hypodermic of ten minims of tincture of veratrum viride, which is repeated every ten minutes until the convulsions stop or the pulse comes down to forty. Then he gives a quart of salt solution by enema, which is quickly absorbed by the rectum, and as the spasm in the arterioles of the kidneys relaxes, the water rushes into them, and in half an hour there will be a copious secretion of urine. He says no chloroform, no chloral and no accouchement forcé are needed, but the woman falls into a quiet slumber, and later there is a normal labor and probably a dead fetus. He says there is some fright when the pulse comes down to forty, but there is nothing to fear.

MANAGEMENT OF PREGNANCY COMPLICATED WITH UTERINE FIBROIDS.

Routh [12] says that danger arises from cases being improperly treated, or not treated at all, but when complications are treated efficiently by modern surgical and antiseptic methods, the mortality is enormously reduced, the chief dangers being:

(1) *During pregnancy*, — rapid enlargement of the fibroids, degeneration of fibroids, abortion with hemorrhage and sepsis.

(2) *During parturition*, — fetal malpresentations, obstruction, hemorrhage.

(3) *During the puerperium*, — degeneration or extrusion of a submucous fibroid, sepsis and secondary infection of the fibroids.

The effect of pregnancy upon fibroids is discussed under the following:

(*a*) Growth of fibroids during pregnancy. He is not at all certain that fibroids as a rule do increase much in size in pregnancy.

(*b*) Atrophy of fibroids during involution of uterus. They may atrophy and entirely disappear during involution of the uterus.

(*c*) Degeneration and extrusion of submucous fibroids after labor. Occasionally after labor a submucous fibroid will degenerate and be extruded without harm. Usually, however, necrosis of the fibroid occurs during the somewhat prolonged period of extrusion, and sapremia or septicemia may result.

(*d*) Secondary infection of fibroids during the puerperium. Infection of fibroids during the puerperium may occur, and fatal peritonitis may result, as the softening during pregnancy renders them very liable to infection.

The effect of fibroids upon a coexisting pregnancy are discussed under the following heads:

(*a*) Do fibroids cause sterility? It is generally believed they do, but he says it seems probable that fibroids are not by any means a frequent cause of sterility, but that it is possibly more true that sterility is a cause of fibroids.

(*b*) Probably fibroids do not predispose to abortion or premature labor, as statistics seem to prove that the proportion of abortions with fibroids is very little greater than the normal average.

(*c*) Fibroids undoubtedly cause fetal malpositions.

(*d*) Fibroids lead to uterine inertia and delayed labor. Also post-partum hemorrhage and adherent placenta are more frequent than in normal labor.

(*e*) Existing fibroids may cause obstruction during labor, but spontaneous elevation of the fibroid out of the pelvis is more likely to take place late in pregnancy or even in labor. Cervical and intraligamentous fibroids are incapable of being elevated.

(*f*) Involution in the puerperium is retarded but not impaired. The lochia is increased and persists longer.

In treatment before fetal viability, attempts should be made to elevate the fibroid by digital or hydrostatic pressure in the Sims or knee-chest posture. Forcible reposition is to be avoided. Induction of abortion has been abandoned. Myomectomy is now the ideal indication for treatment when pressure symptoms develop before fetal viability, but it can only be hopefully undertaken in a small number of cases. Hysterectomy is the procedure where there is real danger in allowing the patient to go to term, or where pressure symptoms are serious and the fibroids are multiple and too deeply imbedded, also, for intractable hemorrhage.

In treatment after fetal viability the indication is to leave things alone so long as the mother's life is not endangered. Reposition may be tried. No attempt should be made to drag a child, living or mutilated, past an obstructing fibroid of any size by forceps or by version. If the patient is in labor, and the obstructing fibroid shows no tendency to rise, or if it is fixed in the pelvis, an operation is inevitable, and except in the case of a cervical fibroid abdominal section is necessary, for symphysiotomy is condemned by all in these cases. Cervical fibroids cannot be elevated, but in some cases they may be enucleated from below.

In treatment after labor hysterectomy may be required in cases where labor has already taken place in fibroid uteri, for post-partum hemorrhage or uterine sepsis with infected fibroids with retained placenta.

TREATMENT IN MEDIUM DEGREES OF PELVIC DEFORMITY.

Kerr [13] says that while it is not difficult to recognize a deformity of the pelvis, it is a matter of very great difficulty to appreciate the exact degree and nature of the malformation, as the means for measuring and estimating the pelvic cavity are so defective. A careful measure-

[12] Brit. Med. Journ., Oct. 3, 1903, p. 798.

[13] Amer. Journ. Obstet., July, 1903.

ment of the pelvis both by hand and by pelvimeter should be made, and an estimate of the size of the child's head attempted, but in certain cases, however, a conclusion as regards treatment cannot be come to until labor has progressed, especially in primiparæ. With a conjugate vera of less than three and one-half inches, he has never seen a woman deliver herself of a normal full-term live child. The lowest limit for forceps he considers as three and one-quarter inches, and forceps should not be applied if the fetal head, after having had time to engage and mold is still movable at the brim. His results with regard to fetal mortality are very much worse with version than with forceps, and his conclusion as regards version is that it is a treatment more dangerous to the mother and with an infinitely higher fetal mortality than forceps.

BIRTH PARALYSES.

Kennedy [14] reports three cases in which he practiced suture of the brachial plexus in birth paralyses of the upper extremity. This procedure is based on the principle that such cases should be dealt with as similar injuries are usually treated. If there is no spontaneous improvement, the seat of injury should be exposed and the condition dealt with on general principles. In one of the author's cases complete restoration of function ensued; in the other two voluntary motion was not restored.

ABNORMAL SITE OF THE AFTER-BIRTH.

Bayer [15] calls attention anew to the fact that the cervix does not behave the same in all pregnancies. In some it develops by unfolding irregularly, and the physiologic stricture becomes spastic in labor accompanied by spasmodic contractions. The after-birth in placenta previa is inserted in the lower pole of the uterus, but not in a correctly regular segment, and hence it develops abnormally. He says a woman who has had considerable hemorrhage during the pregnancy but who arrives at term without much loss of strength stands a better chance of recovery (from placenta previa) with a living child than one whose labor commences at term without any hemorrhage during the pregnancy. The same conditions prevail when the placenta is located in the tubal angle. The uterus forms a "tubal segment" as the walls of the tube expand under the placenta. In case of placenta previa it becomes more or less detached and hemorrhages occur, simulating the phenomena of premature detachment of a normally located placenta. The various conditions are shown in cuts. With a placenta located in the tubal angle the uterus becomes saddle-shaped. No special treatment is required for it, except that the possibility of a pathologic process must be borne in mind.

INDICATIONS FOR FORCEPS OPERATION.

Fehling [16] thinks that injury of the soft parts would not occur if students were trained in forceps operations and repair of injuries by careful suture under the eye of the professor. He adds that no "practicant" is allowed to leave his clinic without having sutured a perineum once or several times. He thinks that there is nothing to prove that the application of forceps leads to hemorrhage from atony. Hemorrhage from lacerations can be easily controlled. Slight lacerations of the cervix occur in nearly every normal birth, and Emmet's operation is usually superfluous. He states that in 815 forceps operations he has held the forceps himself in only ten. He regards feeble contractions as an indication for their use and advocates resorting to them when all the conditions are favorable and the deilvery stage lasts more than three hours.

HYPEREMESIS GRAVIDARUM.

The author [17] reports a case of hyperemesis which became grave during the third month of pregnancy. The induction of abortion was contemplated, but the employment of copious rectal injections of normal saline solution was followed by rapid improvement, and after fourteen days of treatment by this method the patient could retain all kinds of food. The cessation of injections was followed by a return of vomiting, which again disappeared when the treatment was recommenced. A second case is also reported. The writer orders each morning rectal lavage for cleansing purposes, followed by the injection every two hours of about half a liter of warm saline solution, which is retained and absorbed. Four less severe cases were treated in the same way. The symptoms occurred between the second and fourth months of gestation. The pelvic organs were normal in each instance, and there were no manifestations of hysteria. In each case the rectal injections were followed by the cessation of vomiting.

Reports of Societies.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

STATED meeting, Dec. 14, 1903. The President, ANDREW H. SMITH, M.D., in the chair.

DR. SAMUEL G. GANT read a paper on

WATER ANESTHESIA IN OPERATIONS ABOUT THE RECTUM, ANUS AND BUTTOCKS.

A local anesthetic which would prove effective in operations about the ano-rectal region, and at the same time be devoid of toxic properties, would, he said, enable the surgeon to perform most of these operations in his office, and he had accordingly been experimenting for many years in order to find one possessing these advantages. It was thought for a time that Beta-eucaine met these requirements, but even this preparation had not proved entirely satisfactory. His more recent experience, in more than 150 cases of rectal affections radically operated upon,

[17] Behm: Archiv. fur Gyn., 1903, Bd. lxix, H. 2, p. 410 Journ. of Obstet. & Gyn. Brit. Emp., October, 1903, p. 393.

had shown that sterile water, properly injected, is a reliable local anesthetic, — and he was convinced that this is the most desirable agent for these operations, for the reason that it produces an adequate degree of anesthesia, while in no instance has its employment been accompanied or followed by any of the annoying and dangerous complications frequently encountered under the use of cocaine or similar drugs.

Dr. Gant was induced to try distention of the tissues with water to produce local anesthesia in consequence of the following observations: (1) Cocaine, eucaine and other similar solutions were practically inert when distention was not obtained, because of the escape of the fluid through an ulcer, fissure or sinus. (2) Very weak solutions of the same drugs were apparently as effective as strong solutions in all cases where complete distention of the tissues was possible. While experiments with sterile water anesthesia were begun in September, 1901, it is only recently that the technique has been so improved that he has been enabled to use it in a very large majority of his operations, to the exclusion of general and medicinal local anesthetics. Among the cases in which he has successfully employed it are included radical operations for protruding and non-protruding internal hemorrhoids, cutaneous and thrombotic external hemorrhoids, polypi, prolapsus ani, fistulæ of various kinds and marginal and follicular abscesses; excision of perineal cysts, sacral dermoids and lipomata of the buttocks; removal of foreign bodies beneath the skin and mucosa; division of the sphincter ani in cases of constipation where divulsion proved ineffective; fixation of an elongated sigmoid to the anterior abdominal wall; colostomy and exploratory laparotomy.

Technique. — The only requirements for the practice of the procedure are sterile water and a hypodermic syringe fitted with a long, fine, sharp-pointed needle, which, with the syringe itself, should be carefully sterilized. The temperature of the water is unimportant, but warm water is preferable, as causing the least discomfort. Sterile saline solution does not appear to possess any advantage over simple water. The manner of injecting the water varies according to the nature of the operation to be performed. When an incision through the skin is required, a fold of the integument at one extremity of the line of incision is compressed for a few seconds between the thumb and forefinger; this diminishes and often prevents the momentary pain which may be caused by the first injection. The needle is then inserted between the layers of the skin and a few drops of water are slowly injected; this should produce a small, localized distention not unlike a blister, and immediately on its appearance cutaneous anesthesia should occur at this point. Next, the needle is slowly introduced further and further along the line of the cut to be made, care being taken not to go entirely through the skin, and the water is gradually injected as before. When the syringe has been emptied, it is refilled and the needle re-introduced within the anesthetized area, the injections being repeated, as before, until the distention extends the entire length of the line of incision. The needle is then plunged through this distended line and subcutaneous injections are rapidly made until a firm, whitish, ridge-like swelling, about as wide and thick as the index finger, is produced. These deep injections may cause a temporary sense of discomfort, owing to the rapid distention of the subcutaneous tissues. If the procedure has been properly carried out, the skin and underlying tissues can now be incised without pain in almost every instance.

Dr. Gant then gave some details of the methods he employed in various operations, and stated that he did not advocate water anesthetization for deep ischio-rectal, peri-rectal or pelvi-rectal abscesses where extensive cutting and curettage are essential. For external thrombotic hemorrhoids it is requisite to make the injection of sterile water only between the layers of the skin overlying the clot to be removed, while in excising external cutaneous hemorrhoids both the skin and tumors should be distended tightly in order to obtain effective anesthesia. Large internal venous or capillary hemorrhoids can be completely anesthetized within thirty seconds by injecting directly into the center of each tumor sufficient water to distend it tightly and cause it to turn white. Any affection which requires operative procedure to increase the lumen of the anal outlet, or which necessitates incision of the sphincter muscle, may be operated upon under water anesthesia. After the skin and mucous structures up to the margin of the anus have been distended, injections are made into the mucosa, the submucosa, the external sphincter and, if necessary, the internal sphincter muscle. They should be made slowly, as rapid distention of this sensitive region may give rise to considerable discomfort.

Advantages. — Among the advantages of water anesthesia are the following: (1) In the majority of rectal operations there is no necessity of requiring the patient to submit to the annoyance and expense of entering a hospital and undergoing general anesthesia. (2) The rapid distention of the tissues to be incised or removed enables the operator to work quickly, and as the patient is not confined to bed during the after-treatment, but can come to the office to have the dressings made, it economizes the surgeon's time and labor. (3) No annoying or dangerous complications or sequelæ have been observed. (4) Experience has shown that the pain and bleeding following this method are less than when medicinal local anesthetics are used. (5) It eliminates the danger to life from the heart, lung and kidney complications which may result from the use of ether or chloroform, and it avoids the increased pain and hemorrhage due to straining and vomiting after general anesthesia. (6) The only requirements are a hypodermic syringe, a suitable needle and boiled water. (7) The radical treatment of hemorrhoids can be so easily carried out in the physician's office, and with so little danger and inconvenience to the patient, that it should relegate to oblivion the much-vaunted injection treatment, which is always dangerous and uncertain.

Modus operandi. — As the anesthetization of the part occurs almost instantly upon complete distention of the tissues, it would seem probable that the anesthesia is produced by the pressure upon the nerves and their terminations caused by the distention. If the pressure is too quickly induced, however, by too rapidly injecting the water, it may cause considerable temporary discomfort, amounting to pain in extremely sensitive persons.

Limitations. — This method of anesthetization is not practicable for extensive operations, such as are required for excision of the coccyx, the removal of large tumors by excision, or resection of the bowel, or for the relief of complete prolapsus recti, complex horseshoe, recto-vesical, recto-urethral and recto-vaginal fistulæ, very extensive abscesses, or strictures, congenital malformations or other affections located in the upper rectum; neither is it applicable for opening the abdomen in cases where there is a thick layer of fat and the tissues are so loose and flabby that a proper degree of distention cannot be secured.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MARCH 10, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

THE MASSACHUSETTS SCHOOL FOR FEEBLE-MINDED.

THE fifty-sixth annual report of this institution is before us, a report which we always read with peculiar interest. The work of the institution is done so quietly and unostentatiously that the public at large is little aware of the difficulties which must be met and the admirable results which are accomplished in the care and treatment of this difficult class of patients.

At the time of the issue of the report there were 668 feeble-minded persons at the school at Waltham and 132 at the newly instituted farm colony at Templeton, making a total of 800. Of this number 47 are private pupils supported in whole or in part by parents or guardians. The increasing demands made upon the institution are necessitating further accommodations. To this end, under an appropriation granted in 1902, a new dormitory is in process of construction for the accommodation of the older girls. The health of the inmates has in general been good, and the mortality compares most favorably with the death-rate in the community at large. It can no longer be said that the life of the feeble-minded person is short. Possibly this lengthening of the life of these unfortunate persons may be regarded as not wholly a blessing, nevertheless it serves as an excellent demonstration of the faithful care which this most helpless class is receiving.

The school department, about which the other branches of the institution center, is an outgrowth, as is now generally known, of the first organized attempt in this country to educate the idiot as far as may be. This conception and its consummation was due to the persistence of Dr. Howe. Naturally his ideas have been modified, particularly on the religious side, but the fundamental principles which he inaugurated are still active and fruitful. The colony at Templeton, to which we have before alluded editorially, has proved a complete success. It accommodates feeble-minded boys and men and provides for them active and at the same time useful employment.

The superintendent, Dr. W. E. Fernald, calls attention in his report to many facts of interest. It is encouraging, in the first place, to observe that of 97 admissions 51 were young, teachable pupils capable of much improvement. There were 269 applications for admission during the year, many of whom have been promised accommodation as soon as the new dormitories are completed. Attention is also called to the fact that one of the functions of a school for the feeble-minded is to afford clinical instruction for students of medicine and others interested in the psychological problems which the idiot class presents.

The hospitality of the management has been appreciated by the medical schools of the city as well as by classes from Wellesley, Harvard College and the state normal schools, whose purpose is rather psychological and pedagogical than medical. We have long felt that most valuable opportunities for instruction near at hand are too much neglected, both by teachers and students. The amount of information which may be obtained by several visits to the Waverley School, or to allied institutions, is very much greater than can be had by ordinary methods of instruction. Not only are many patients of a similar sort gathered together in one place, but the mental impression which such visits make upon the student's mind is often incalculably great. If the institutions are willing to offer this hospitality to students, it should be accepted far more completely than is at present the case. The Waverley School has subserved a further and wide-reaching function in providing information on methods of teaching this type of children, and in serving as a source of information for physicians or parents who seek advice as to the diagnosis and home treatment of feeble-minded or otherwise abnormal children.

Each year sees a widening of the scope of this admirable institution. It is not only caring for an outcast portion of the community, but is actually making the persons who comprise it use-

ful in varying degrees to themselves and to the state. Such a work deserves the warmest commendation.

THE ISLANDS OF LANGERHANS.

The recent work of Opie on the Islands of Langerhans has attracted much attention to these previously little understood structures. Opie showed that certain cases of pancreatic diabetes have a definite relation to lesions of the islands. This observation has been confirmed by other investigators and is based upon the assumption that these structures have a physiological function distinct from that of the rest of the pancreas, and are concerned particularly with carbohydrate metabolism, hence their importance in relation to diabetes. It has been shown by Ssobolew and Schulze that after ligation of the pancreatic duct in animals the glandular portion of the pancreas atrophies and is replaced by fibrous tissue, but that the islands are unchanged and no sugar is excreted. Under similar conditions produced by disease in man Opie has observed the same result.

Dr. R. M. Pearce, in a recent number of the *Albany Medical Annals*, takes up again the study of the Islands of Langerhans in relation to congenital syphilitic pancreatitis. Dr. Pearce finds in the study of the pancreas in congenital syphilis that the same picture of chronic inflammation is produced described by Opie as the result of obstruction of the duct with similar persistence of the islands. This persistence of the islands has not been generally recognized in young children, owing to the rarity of post-mortem examinations, and also that attention has not been hitherto particularly directed to these structures. Dr. Pearce has filled a gap in our knowledge by studying the development of the islands in human embryos and has by this study brought out certain interesting considerations with relation to the syphilitic organ.

The first study of syphilitic pancreatitis was made in 1875 by Birch-Hirschfeld. Since then a considerable number of cases has been reported. The lesion is characterized by an increase of connective tissue compressing and causing atrophy of the glandular elements. Schlesinger regards the increase of connective tissue as of perivascular origin. Dr. Pearce, through the courtesy of various physicians, has been able to examine a number of cases of pancreatitis of the syphilitic form in infants. He finds as a most striking feature of the alterations a persistence of the Islands of Langerhans in spite of a general destruction of the glandular acini. The islands apparently show no evidence of degeneration or atrophy or an ingrowth of connective tissue, from which it is assumed that they are anatomically independent. Certain histological evidence goes to show that in their early development they are in connection with the acini, and that their development is interrupted in the case of syphilis by an ingrowth of connective tissue leading to the atrophy of the glandular tissue and sparing the more resistant islands. Dr. Pearce, in his embryological work, has substantiated this point of view, before reached by Opie.

From a comparison of the pancreas under normal conditions and as affected by the presence of syphilis, it appears that syphilitic infections occur in the third or fourth month while the islands are still connected with gland tubules. In general the microscopic picture of the normal pancreas at the end of the third month is similar to that of the syphilitic organ at the end of the sixth or seventh month, particularly with regard to the stage of development of the islands. The ultimate factor in the resistance of the islands to disease is supposed to be their abundant blood supply. Dr. Pearce's careful study, although, as he says, adding nothing essentially new to our conception of the structures under consideration, nevertheless is a further link in the chain of evidence which has been accumulating during the past few years, and will tend to establish upon a still firmer basis the significance of the hitherto little understood Islands of Langerhans.

MEDICAL NOTES.

A Bequest to Consumptives' Home. — By the will of the late Miss Sarah Schermerhorn the Denver, Col., Home for Consumptives receives $50,000.

Pneumonia and Consumption in Chicago. — For the week ending March 12, the deaths from pneumonia in Chicago had decreased and those from consumption had increased quite sharply.

German Congress of Internal Medicine. — The twenty-first annual German Congress of Internal Medicine will be held at Leipsic, April 18 to 21, under the presidency of Dr. Merkel of Nuremberg. The main topic of discussion will be arteriosclerosis.

Address on Dr. Joseph O'Dwyer. — W. P. Northrup, M.D., addressed the J. C. Wilson Medical Society of Philadelphia on Feb. 19. Subject:

"Joseph O'Dwyer, M.D. The method of his work on Intubation; The measure of his success; The interest of both to young practitioners."

CENTENARIANS. — Mrs. Sarah Coover, said to have been born in 1798, died March 1, at Mechanicsburg, Pa. Her extreme age, nearly one hundred and six years, is said to be well attested.

Mrs. Sarah B. Chapman has also recently died at the reputed age of one hundred and one years in Bethel, Vt.

THE BUTLER TYPHOID EPIDEMIC. — The emergency hospital for the purpose of treating typhoid patients at Butler, Pa., has been closed. In upwards of 1,300 cases 115 deaths occurred. It is reported also that nearly 10% of the number of nurses employed were infected during the course of their service.

MEDICAL PRACTICE BY FOREIGNERS IN SPAIN. — The question of medical practice in Spain by holders of foreign diplomas has recently formed the subject of animated debates in the Spanish senate. The discussion has so far led to no definite conclusion, but from the reports that have been published it may be gathered that a foreign doctor can at present practice his profession in Spain without the necessity of submitting to any further examination.

FRENCH CONGRESS OF CLIMATOTHERAPY AND HYGIENE OF TOWNS. — As previously announced, the first session of this Congress of Climatotherapy and Hygiene of Towns will be held at Nice the 4th to the 9th of April, under the presidency of Professor Chantemesse of Paris. It is officially announced that members of the congress will be allowed large reductions over many of the railway lines of France and Corsica, and also on certain of the steamship lines. Italy has also granted reductions in railway fares, and many hotels have adopted similar reduced prices. The members of the congress will officially visit Monaco, Mentone, Cannes and Grasse. The Prince of Monaco will hold a reception at the palace, and there will be a gala performance at the casino. Other excursions and festivities will likewise take place. In order to take part in the congress it will be necessary to remit to the treasurer, Dr. Bonnal, 19, Boulevard Victor-Hugo, Nice, the amount of twenty francs, accompanied by the subscriber's visiting card, titles, etc.

Further information will be supplied by Dr. Hérard de Bessé, General Secretary, Beaulieu s. m. (Alp.-Marit.).

DEATH OF DR. PETER DETTWEILER. — Dr. Peter Dettweiler died Jan. 13, 1904, after an active life devoted largely to the advancement of the treatment of tuberculosis. He was born in Hesse, Aug. 4, 1837, and took his medical degree in 1863. While serving as surgeon in the Franco-Prussian war, he contracted tuberculosis, underwent sanatorium treatment, recovered his health and became assistant of Dr. Brehmer at Goerbersdorf, where he had formerly been a patient. After a service of six years at this institution, he founded the sanatorium at Falkenstein, which has since attained a very wide reputation as a pioneer in sanatorium treatment. Dr. Dettweiler was the first to advocate rest in the open air, to establish the first sanatorium for consumptive poor and in general to supply the stimulus which has since resulted in the development of this line of treatment.

He has written several works on the general subject of the treatment of tuberculosis, and has long been looked upon as the leader in the rational treatment of the disease. He was personally attractive, had an unusual influence over his patients and was always cordial in his treatment of visitors to his sanatorium.

ADIRONDACK COTTAGE SANITARIUM. — Among many statements of interest in the nineteenth annual report of the Adirondack Cottage Sanitarium, the following are worthy of quotation:

"Of 1,500 cases which have been discharged from two to seventeen years ago, 334 could not be traced, leaving 1,166 which have been traced. Of these, 46.7% are still living — 31% are known to be well at present, in 6.5% the disease is still arrested, 4% have relapsed, 5.2% are chronic invalids — and 53.3% are dead. Thus we learn that 31% of all cases discharged from two to seventeen years ago have remained well."

. . . . .

"The work done by the Sanitarium during the past year may be summed up briefly as follows: Two hundred and ninety-eight patients have been treated. To 257 of these the institution has furnished the best possible means of restoration to health at a nominal cost, and to 41 entirely free of cost to them.

"As a further means of increasing the beneficent work of this institution a plan has been devised, deserving of general sympathy and cooperation, whereby persons partially recovered, who yet are not able to do the work of persons perfectly well, may still be provided with remunerative employment in proportion to their

strength and capacity. To meet this need a co-operative employment bureau has been established, and persons interested are requested to indicate to this bureau possible positions for tuberculous persons capable of working, but who are in no way a menace to others."

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon March 9, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 47, scarlatina 33, typhoid fever 12, measles 186, smallpox 0.

BEQUESTS TO HOSPITALS. — Through the will of the late Mr. George B. Upham of Milton, Mass., the Massachusetts General Hospital receives $10,000.

Mr. Nathaniel A. Moody, who recently died at his home in Waltham, Mass., makes the Waltham Hospital the sole ultimate beneficiary of his estate, valued at about $20,000.

SHARON SANATORIUM. — On recommendation of the directors, it was voted at the annual business meeting to change the name of the Sharon Sanitarium to that of Sharon Sanatorium.

The president, Prof. William T. Sedgwick, presided, and the following-named directors and officials were elected: President, William T. Sedgwick; treasurer, Nathaniel H. Stone; secretary, Mrs. Charles A. Porter; directors, Augustus Hemenway, Rev. Edmund F. Merriam, Arthur Dehon Hill, Mrs. Henry P. King, Mrs. W. T. Sedgwick, Vincent Y. Bowditch, M.D., Robert W. Lovett, M.D., L. Vernon Briggs, M.D.; medical director, Vincent Y. Bowditch, M.D.; consulting physician, Frederick I. Knight, M.D.; resident physician, Walter A. Griffin, M.D.; matron and superintendent, Miss Alice R. Hodges.

It was stated at the meeting that the percentage of patients — women of limited means with early symptoms of consumption — who have regained their health since entering the institution from the opening in February, 1891, and up to two years ago has been large. Generous public support is solicited to supply the large yearly deficit.

NEW YORK.

GIFT OF A PARK TO UTICA. — By the will of William G. Helligan, late president of the Herkimer County Bank, the city of Utica, N. Y., comes into possession of a beautiful park of forty-five acres and a fund of $12,000 to maintain the property.

RESIGNATION OF DR. PETERSON. — Dr. Frederick Peterson of New York, President of the State Commission in Lunacy, has presented to Governor Odell his resignation as a member of that body. The reason assigned is that the duties of the position interfere to too great an extent with his private professional work.

APPOINTMENTS IN MEDICAL DEPARTMENT, COLUMBIA UNIVERSITY. — At a meeting of the trustees of Columbia University held March 7, the following appointments in the medical department were announced: Dr. Edwin B. Cragin, Professor of Obstetrics, to fill the chair of Gynecology (made vacant by the resignation of Dr. George M. Tuttle) until further action by the trustees; Dr. Henry McMahon Painter, Clinical Professor of Obstetrics; Dr. Gorham Bacon, Clinical Professor of Otology, vice Dr. Albert H. Buck, resigned; Dr. William K. Simpson, Clinical Professor of Laryngology, vice Dr. George M. Lefferts, resigned. The trustees have established eight scholarships in the College of Physicians and Surgeons, each of the money value of $250 annually. Four of them will be known as William N. Vanderbilt scholarships, in memory of Mr. Vanderbilt's gifts to the school, and the remaining four will be faculty scholarships.

CROWDED HOSPITALS. — All the hospitals in the city are crowded this winter to an almost unprecedented extent, principally owing to the prevalence of pneumonia and other chest diseases. Dr. John W. Brannan, President of the Board of Trustees of Bellevue and Allied Hospitals, has made the following statement in reference to the existing conditions: "This overwhelming demand upon the hospitals is very largely the result of the extremely severe weather we have been having. Persons physically strong and able-bodied, who scarcely knew what it meant to be sick a day since they were born, have yielded to the trying weather of the past few weeks. There is, however, another cause which has had a good deal to do with the situation. The poorer people find times so hard that they are unable to get work and to provide for their families as they used to do. Consequently, when any member of the household becomes ill, he is at once sent to a hospital, as a matter of necessity." In order to relieve the present congestion, Dr. Brannan announced that a number of tents, similar to those at the Metropolitan Hospital tuberculosis infirmary, would be put up without delay. These tents, so-called, will be partly of wood and partly

of canvas, and will be heated either by stoves or steam pipes. "The only permanent relief for Bellevue, however," he said, "will come when it gets its new building, but, of course, that will not be for some time yet. We are enlarging the other three hospitals, and this work will be pushed with all possible dispatch."

Miscellany.

A CONTRAST.

A CORRESPONDENT sends us the following extracts from the second volume of Viscount Wolseley's *Story of a Soldier's Life* published recently. They deserve to be put side by side:

No one ever fell sick [on the Red River expedition]. I was asked to have our senior doctor promoted when the expedition came to an end, but refused, because he had had nothing to do, there never having been any sick for him to cure (p. 208).	So ended the Red River expedition. . . . As far as fighting was concerned it was a bloodless campaign, and although great physical difficulties were encountered and manfully overcome by the troops employed, not a life had been lost (p. 223).

Lord Wolseley does not go on to say that the honors which came to him as the leader of this bloodless expedition were undeserved, yet the analogy is perfect. If the senior doctor had nothing to do because nobody was sick, the senior fighter can have had nothing to do because nobody fought. How long will it be before military commandants and reconstitution committees begin to take a rational view of hygiene as an integral part of military administration, without which the most beautiful scheme with family trees and new offices and new titles for old offices must come to the ground when put to the actual test of war? — *British Medical Journal.*

REPORT OF THE BUTLER, R. I., HOSPITAL.

THE annual report of the Butler Hospital shows that there were in the hospital Jan. 1, 175 patients, of whom 90 were women and 85 men. During the year 56 women and 40 men were admitted, making the entire number of patients under treatment 271. Dr. Blumer, the superintendent, makes a vigorous plea for a more rational point of view regarding the popular attitude toward mental disorders, and draws attention to the fact that the Butler hospital is more and more fulfilling the function of an institution for the care of persons not to be regarded as insane.

Dr. Blumer says in part:

It cannot be too often protested that there is no stigma of insanity. Indeed, in these New England communities of ours, where brains are more apt to be highly organized than in less favored parts of the country, it may even be a mark of distinction to possess a mind of sufficient delicacy to invite damage under the stresses of life, while the stolid and exceedingly commonplace Philistine who calls his brother Raca conserves unscathed his modicum of gray matter and is serenely unmindful of the scriptural consequences of his somewhat absurd detraction. Year by year and little by little the patient champion of the claims of the insane to respectful consideration as invalids makes headway against ignorant or loose conceptions of the kind of which complaint is here made. Slowly the idea that insanity is a symptom of disease, no less than toothache, and no more disgraceful, is gaining ground. People are becoming familiar with forms of mental derangement other than those which have extreme outward manifestations and know that nowadays the patient goes to a hospital because he is sick and in need of treatment, and not because his conduct has made him a menace to himself or the community. A favored few now apprehend that there is no essential difference between nervous and mental diseases, the latter merely showing a greater prominence of the mental symptoms. This growing perception of essential unity marks a welcome advance, because the neurosis was wont always to bear herself with a strut, and even looked down upon her bigger sister, the psychosis, as of a different and lower order.

THE VALUE OF EXERCISE.

JAY W. SEAVER, M.D., of Yale University, President of the Chautauqua School of Physical Education and of the American Institute of Physical Culture, spoke informally before the physicians of Boston and vicinity, at the rooms of the institute, 29 Beacon Street, Boston, Saturday afternoon, March 12.

Dr. Seaver has the unique distinction of having personally made a physical examination of over 30,000 persons, and he has in his possession complete records of their measurements. He referred to exercise as a necessity of life, just the same as sunlight, fresh air and food, because no healthy animal grows into vigorous maturity without performing many movements that are in themselves useless and unnecessary so far as accomplishing work is concerned, but the movements are taken from an innate restlessness that makes the young child play instead of rest. All play is founded on physical activity, and this activity becomes recreative, restful and helpful, according to the needs of the body. Again, exercise is a therapeutic means that cannot be ignored. For over a hundred years attention has been given to what has been called medical gymnastics in the treatment of various forms of disease, and the method has gradually grown in the estimation of medical men until it is the chief agent used in treating many cases of deformity, malnutrition and nervous conditions. Again, exercise may be looked upon from the esthetic standpoint, as a means of producing a more symmetrical and artistic physical development, but more especially in producing a graceful carriage and a control of the body. Emphasis, however, was laid upon exercise as a developmental and therapeutic measure, a means of securing such strength and activity as is characteristic of health and ability to do the work of life. This is accomplished largely through the influence that exercise has upon the nervous system, in giving it a normal outlet for the force that is generated in the brain; as it were, putting an implement in the hands of the brain for the accomplishing of its purpose; and, in the second place, it improves the circulation, so that each part of the body has its due amount of nutrition, and its waste material is swept away, so that the tissues are not poisoned by the products of ordinary wear and tear. The problem of nutrition to-day is not so largely a matter of abundance of food as it is an economic use of food by the system, and this economy is carried out by adequate circulation that eliminates waste and overcomes local stagnation. Modern life has its decided tendency to limit the physical activities, and many of the ills that require the attention of physicians are due to the physical restraints that encumber life. The modern business man does not get his

morning walk to his place of business; his communications with other business men are carried on over the telephone, and the brain in general attends to a multitude of details that in previous generations would have been mixed in with a large number of physical activities that would have reacted favorably upon his general nutrition. Now, he must secure exercise of his muscles in some artificial way. He cannot even spend the time to attend a gymnasium, and it becomes necessary for him to have a routine of movements prescribed by some one who has made a study of physical conditions and the exercises that will be most helpful for each particular case, in exactly the same way that a physician selects from a large number of medicines the ones that his judgment decides will be beneficial to the patient, or he prescribes a diet suitable for his physical needs.

To acquire a ripened judgment as to suitable exercises several things are necessary:

First, there must be a thorough training in the knowledge of the anatomy and physiology of the human body.

Second, there must be a practical knowledge of exercise and its various reactions upon the body.

Third, there must be a knowledge of the pathological conditions involved in any abnormal state, and an appreciation of how these abnormal conditions may be modified by the various forms of exercise.

Fourth, there must be experience in the prescription of exercise, so that a careful estimate may be made of the personal idiosyncracy of each pupil, and such exercises given as shall produce the desired result. The body must be made not only strong muscularly, but it must be trained to work smoothly. The excellence of any machine does not depend upon the great strength of some few of its parts, but its excellence will depend largely upon the smooth and co-ordinate movement of each part. So in the human body the mere possession of great muscular strength is of no special value, but a fine co-ordinate action of all the parts constitutes perfect health, and this should be the aim of every individual, as it certainly is the aim of the American Institute of Physical Culture.

THE BALTIMORE TUBERCULOSIS CONFERENCE.

At a conference held in McCoy Hall on the evening of Jan. 28, presided over by Prof. William H. Welch of Baltimore, at which a number of representative physicians interested in the study of tuberculosis from various parts of the country were present, the following motion by Dr. H. M. Bracken of St. Paul, Minn., and amended by Dr. William S. Thayer of Baltimore, was unanimously adopted: "Moved that the chair be authorized to appoint a committee, with power to act, to consider the conditions existing with regard to the proposed tuberculosis congress and other national antituberculosis associations in the United States; also to consider the formation of a national committee to represent this country at the International Congress at Paris, and that the members of this conference will abide by the action of the committee — also that this committee have power to add to its membership."

In accordance with this motion Prof. William H. Welch appointed the following gentlemen on this committee: Prof. William Osler, Baltimore, Md.; Dr. Edward L. Trudeau, Saranac Lake, N. Y.; Dr. Theobald Smith, Boston, Mass.; Dr. J. G. Adami, Montreal, Canada; Dr. Vincent Y. Bowditch, Boston, Mass.; Dr. S. A. Knopf, New York City; Dr. Mazyck P. Ravenal, Philadelphia, Pa.; Dr. Arnold C. Klebs, Chicago, Ill.; Dr. Edward G. Janeway, New York City; Dr. Henry Barton Jacobs, Baltimore, Md.; Dr. H. M. Bracken, St. Paul, Minn.; Dr. Lawrence F. Flick, Philadelphia, Pa.; Dr. Herman M. Biggs, New York City.

A meeting of this committee was held in New York on the evening of Feb. 27, and various plans were discussed, but it was voted to take no definite action till another meeting, to be held probably in New York early in April, when it is hoped that some final action will be taken towards forming a national committee to represent this country at the International Congress at Paris.

Correspondence.

ALCOHOL AND ALCOHOLISM.

Boston, Feb. 21, 1904.

Mr. Editor: I should like to call the attention of your readers to a bibliography of the scientific literature of the world upon the subject of "Alcohol and Alcoholism" just published at Berlin under the editorship of E. Abderhalden with the collaboration of thirty or forty physicians on both sides of the Atlantic. It is a book of 500 pages and contains about 12,500 titles so admirably systematized that any one who wishes to lay his hand upon more important references on any branch of this subject can easily do so. In the selection of articles for this work the collaborators have aimed to exclude all that was not of definite scientific value. In one section of the work out of upwards of 200 articles examined, only fourteen were chosen on account of the ephemeral character of the remainder. What we have in this bibliography, therefore, is a list not of all that has been written on the subject, but only of all that is worth while.

The work is divided into two main sections, the first dealing with the scientific and medical aspects of alcohol; the second with its sociological bearings. In the first section we have about 1,500 titles referring to the *chemistry* of alcohol and alcoholic beverages, more especially the process of the preparation and fermentation of liquors and the organisms used in this process. One of the subordinate chapter headings in this section bears this interesting title: "Spontaneous Changes and Diseases of Alcoholic Liquids. Pathology of the Organisms used for the Preparation of Alcoholic Drinks."

The next subdivision includes the psychological and toxicological effects of alcohol and alcoholic beverages, the absorption, metabolism and excretion of the drug and its influence upon the functions of the nervous, muscular, respiratory and circulatory apparatus (about 750 titles in this section). Later divisions are concerned with the therapeutical effects of alcohol (about 700 articles), its pathological effects (something over 2,000 references) and its psychological effects (also about 2,000 references). The concluding section of the first part of the book is concerned with the therapeutics of alcoholism and the diseases resulting therefrom (about 1,500 references).

In the sociological chapters of the work the spread of alcoholism in different countries, the work done to combat it both by the state and by private associations and the statistics of its production and consumption are represented.

The work is excellently arranged, full use being made of different varieties of type as an aid to classification and arrangement. Paper and print are excellent. Altogether a very useful work.

Very truly yours,

Richard C. Cabot, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, FEB. 27, 1904.

CITIES.	Population Estimated, 1904.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported, 4,325; under five years of age, 1,123; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 906, acute lung diseases 1,068, consumption 429, scarlet fever 55, whooping cough 8, cerebrospinal meningitis 8, smallpox 12, erysipelas 17, puerperal fever 20, measles 31, typhoid fever 60, diarrheal diseases 132, diphtheria and croup 89.

From whooping cough, New York 2, Philadelphia 2, Baltimore 1, Pittsburg 1, Lawrence 1, Holyoke 1. From smallpox, Philadelphia 12. From cerebrospinal meningitis, New York 5, Baltimore 1, Somerville 1, Chelsea 1. From erysipelas, New York 8, Chicago 3, Baltimore 2, Boston 3, New Bedford 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,425, for the week ending Feb. 13, the death-rate was 18.4. Deaths reported, 5,396; acute diseases of the respiratory organs (London) 165, whooping cough 182, diphtheria 61, measles 93, smallpox 7, scarlet fever 31.

The death-rate ranged from 6.0 in Smethwick to 29.2 in Newport (Mon.); London 17.7, West Ham 18.6, Brighton 16.9, Southampton 16.2, Plymouth 17.4, Bristol 16.9, Birmingham 22.8, Leicester 18.8, Nottingham 19.1, Liverpool 20.9, Bolton 21.7, Manchester 23.0, Salford 20.7, Bradford 17.7, Leeds 21.2, Hull 16.4, Cardiff 17.2, Rhondda 27.7, Wigan 19.9.

METEOROLOGICAL RECORD.

For the week ending Feb. 27, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

DELAYED PUBLICATION. — The strike, now happily at an end, among printers and pressmen is responsible for continued delay in issuing the JOURNAL.

RECENT DEATHS.

HENRY ALBERT RUNDLETT, M.D., of Brooklyn, N. Y., died from pneumonia on March 8. He was graduated from the Harvard Medical School in 1887, and was in the forty-eighth year of his age.

VERRANUS MORSE, M.D., of Brooklyn, N. Y., died on March 9. He was born in Springfield, N. H., in 1818, and was graduated from Dartmouth College in 1845, and from the Medical Department of the University of the City of New York in 1849. Dr. Morse was one of the founders of the Young Men's Christian Association in New York City, and for many years was prominently identified with the work of the society.

MOSES D. KNIGHT, M.D., of Clinton, Hunterdon County, N. J., died on March 6 at the age of seventy years.

CHARLES T. WHYBREW, M.D., of New York, a graduate of the College of Physicians and Surgeons in the year 1870, died on March 8.

FORCIBLE CORRECTION IN LATERAL CURVATURE OF THE SPINE.[1]

Fourth Paper.

BY ROBERT W. LOVETT, M.D., BOSTON.

The problem to be met in the treatment of severe lateral curvature with fixed bony changes is a perfectly definite one. A clear understanding of the obstacles to be met and of the means at our disposal for meeting them is essential to successful treatment.

The spinal column having curved to one side has in the course of years become fixed in the deformed position. In addition to the side curve, a rotation or twist in the length of the column has occurred at the seat of the main and compensatory lateral curves. As the result of the maintenance of the vicious position over a long period of time, covering part of the period of growth, changes in bones, muscles, ligaments and intervertebral discs have occurred. The individual vertebræ have become compressed on one side and twisted by the rotation. The ligaments and muscles have become adaptively shortened on one side and stretched on the other and the intervertebral discs to a greater or less extent have become compressed on one side. The region of the vertebral column involved by the curve has lost its normal mobility and is partly or wholly stiff. There are secondary changes in the thorax and its contained organs but these are secondary also in importance.

It is obvious that in the upright position gravity works to increase the deformity by exerting pressure upon the concavity of the curves already atrophied by an abnormal weight-bearing. Of the twenty-four hours in each day only some eight or ten at most are spent in recumbency. During the remaining fourteen or sixteen hours the vertical position is assumed and gravity is at work.

In formulating the relative value of the treatments proposed for the rectification of these severe structural changes in scoliosis it may not be unfair to consider the question on general grounds by comparing the condition, so far as the resultant deformity is concerned, to the common condition known as knock-knee. The bodies of the vertebræ in the curved part of the spine have become affected in their growth so that they are smaller on the side of the concavity of the curve and have become wedge-shaped and the planes of their articulation with each other have become oblique to the horizon; that is, a condition mechanically to be compared to knock-knee exists between each two of the deformed vertebræ.

It may be permissible to consider for a moment the means of correction at our disposal in knock-knee to see what analogous methods may be useful in correcting an analogous mechanical condition in the spine.

[1] Read before the Boston Society for Medical Improvement, Dec. 21, 1903.

The means to be used in knock-knee are: (1) Massage, gymnastics and manual manipulation; (2) braces; (3) prolonged recumbency in a corrected position; (4) operation.

(1) Gymnastics, etc. If one took a girl of twelve with bony deformity sufficient to cause knock-knee and for an hour daily massaged, manipulated and exercised the legs one would expect but slight if any improvement. Even a treatment extending over several hours a day with the use of apparatus to localize and make more effective the exercises would hardly seem likely to prove efficient in the long run.

Gymnastics. The purely gymnastic treatment of severe structural scoliosis is to-day being largely pursued by two classes of persons. First by irresponsible masseurs and medical gymnasts who hold as a tradition that gymnastic exercises are curative or at least helpful in scoliosis, and, second, by competent surgeons who do not believe in corsets or supports.[2] The former class serves only to bring the legitimate use of gymnastics for scoliosis into disrepute; the latter class use the gymnastics understandingly and on the whole take a pessimistic view of the results to be obtained in severe scoliosis. The exercises of course are helpful so far as they go. They improve the muscular condition and by the development of the muscles of the back and sides they obscure the curve of the spinous processes and equalize the contours of the body. Occasionally such gymnastics produce marked improvement in the patient's attitude.[3]

But to expect free muscular exercises to straighten, to any extent, curves caused by deformity of the vertebral bodies seems unreasonable.

Gymnastic treatment after forcible correction and in connection with effective support is, however, of the greatest value and may well be reckoned one of the essentials of successful treatment.[4]

Intermittent force and gymnastics. The use of intermittent corrective force in the treatment of the severer forms of lateral curvature remains to be spoken of. In connection with the use of gymnastics the combination forms to-day probably the most common treatment in use here and in Europe in the hands of competent specialists.

There are two aims of treatment to be kept in mind in this as in every form of treatment. The spine must be made more flexible and muscles must be developed to hold the improved position made possible by this increased flexibility. The treatment may be therefore divided into two heads: (1) Flexibility; (2) correction.

Flexibility is obtained by hanging and head suspension, active bendings and passive stretchings to one side; by the application of side force during suspension by the appliances of Hoffa,[5] Weigel,[6] Wullstein[7] and Schede,[8] and by the appliances of Schulthess.[9] All these measures strive by their daily use to loosen up

muscles and ligaments to enable the patient to assume a more correct position. They are of course useless without supporting and corrective muscular development, for flexibility gained without means of retaining it does more harm than good.

The correction or other part of the treatment is to be obtained by general and special muscular exercises, including the raising of heavy weights, etc. But free standing exercises are with difficulty accurately localized where they are needed and compensatory curves are likely to be increased.

The best development of such corrective work is to be found in the forms of apparatus devised by Schulthess, where resistive and active exercises are given in appliances which accurately localize the movement and control and regulate its force. They are described in detail by him.

(2) *Braces and corsets.* It is pretty generally admitted that the corrective effect of braces in straightening the curves in severe scoliosis is a very slight one. For the most part they are now used for this purpose by instrument makers who sell appliances which are largely worthless and by physicians unfamiliar with the problem of treatment who refer their patients to the instrument shops.

To compare the condition again with knock-knee one would expect but slow gain from the use of braces in a case of knock-knee in a child twelve years old. Yet here the femur and tibia furnish excellent levers for the use of corrective force and the force can be applied directly to the inner surface of the knee.

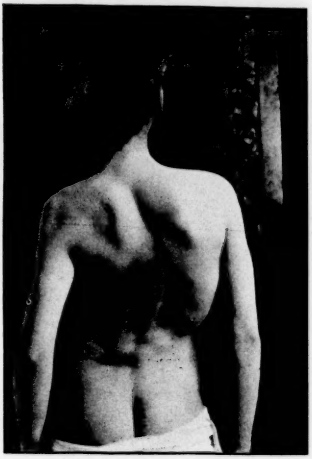
In severe scoliosis no such direct application of force is possible, as side pressure must be transmitted through the ribs and on account of the mobility of the column a long or accurate leverage is impossible as far as corrective force is concerned.

Braces and corsets are, however, of the greatest use in maintaining the correction obtained by the use of force or by other means. The matter of their best form and construction is discussed at length in other places and many admirable forms exist.[10]

(3) *Prolonged recumbency* in the treatment of scoliosis is the relic of a bygone tradition and need not be discussed, being rarely advocated at present.

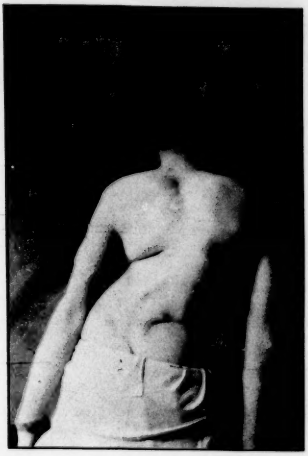
(4) *Operation.* The question of the operative relief of scoliosis is still subjudice. An operation was proposed by Volkmann in 1889, consisting of resection of the ribs on the convex side of the curve, and this operation was also performed by Hoffa[11] with fair result. A similar operation was thought out by N. M. Shaffer of New York about fifteen years ago and spoken of to the writer at that time but never put on record, as the general surgeons to whom it was referred refused to sanction it.[12]

The latest and best operative correction has been obtained by Hoke[13] of Atlanta, Ga., who resected the ribs on the convex side of a girl of nineteen and lengthened those of the concave side in a severe dorsal curve. By the application of a corrective jacket great improvement was obtained.



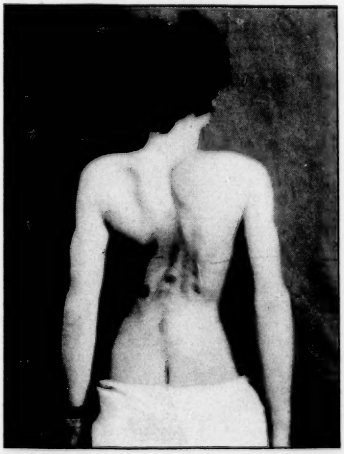
These forms of treatment excepting the operative are not, however, new and have been tested by years of use, and the best comment on their value is to be found in the divided opinion of writers as to which is the best, and in the frequent expressions from competent persons of skepticism as to any great improvement to be expected in severe scoliosis under any therapeutic measures.[14]

It remains, therefore, to look the ground over once more to see if in the application of general surgical principles there is not some more rapid, rational and effective way of attacking the deformity than the methods described.



Of factors making for spontaneous improvement there are none so soon as a certain stage of the deformity is reached. Of conditions to be utilized for the improvement there are two; one, of great significance, was elucidated by the experiments of Wullstein.[15] Some young dogs were kept for months with the spines laterally flexed by means of bandages and springs. At the end of this time true lateral curvature with marked bony deformity of the type described above was present. It would seem fair to state from this that growth in a distorted position of the spine tended to produce deformity of the vertebræ at the points of greatest pressure and that Wullstein's experiment needed only to be reversed to produce improvement in the severer cases of curvature in children still growing.

The second consideration bearing on the treatment is to be found in certain procedures in the manipulation for club foot, in which by forcible manipulation with the hands[16] or a lever[17] a distorted foot with abnormally shaped and improperly developed bones is made by a few minutes' forcible stretching to assume an approximately correct position. If it is held long enough in the improved position, diminution of the deformity is secured. Two conclusions from the above-mentioned facts seem to me to bear upon the question under discussion: (1) Forcible manipulation can immediately stretch muscles and ligaments where the bones are avowedly deformed and seriously misshapen and can secure a temporary change in bony relations; (2) abnormal pressure from abnormal position during the period of growth will modify the shape of bones and stretch muscles and ligaments.



To put it still more simply the best chance of improvement in cases of severe scoliosis would seem to be (1) to use severe force to secure an improved and if possible an overcorrected position temporarily; (2) to retain as much as possible of the position thus secured during some part of the growing period. It is perfectly obvious that for this purpose a high degree of force will be necessary, especially in the case of adolescents. This force must be accurately localized during its application and the retention apparatus must be accurate and capable also of exerting retentive force of rather high degree.

Under Treatment by Retentive Corset and Exercises.

As to how such force can best be used two mechanical conditions bear upon the application of force to the deformed and curved spine.

The least economical use of force in straightening, for example, a bent stick is to pull the two ends away from each other, *i.e.*, to straighten it by a pull in its length. The most economical use of force to straighten it is to take it by the two ends and press the point of greatest convexity against some resisting point which shall push it straight. The relative force exerted will be recognized if one is reminded how easy it is to break a bent stick by striking it on the knee while one hand holds each end and how very difficult it would be to break the same stick by a pull in its length.

Again if one wishes to secure the greatest side displacement in a flexible rod, such displacement is more easily secured when the rod is not stretched in its length. If a rubber tube, for example, is fastened to a table by two pins, one at each end, and is not put on the stretch the middle of it can easily be pulled an inch to one side by the forefinger. If, however, it is pinned to the table by two pins separated enough to hold it on the stretch it will require much more force to displace it one inch to the side. The same is true of a strip of sponge rubber or a piece of rattan.

To be sure that this theoretical consideration applied to the human spine the following experiment was made at the Harvard Medical School by the courtesy of Prof. Thomas Dwight.

A young male cadaver was laid on the face and straps passed around the body at the level of the right shoulder and the right hip. These straps were then fastened to the left side of the table holding the shoulder and hip against pressure from the left. A strap was then passed around the left side of the thorax and by means of a spring balance pulled to the right. The side deviation of the spine was then measured at four levels, the measurements being taken from a base line connecting the cervical spine and the sacrum. The measurements were all made from pins driven into the spinous processes. Three experiments were made with a side pull of 25 lbs. and the results were recorded.

A Sayre head sling was then put around the head of the cadaver still lying on the face and a traction force of 75 lbs. was made, the feet of the cadaver being fastened to the table. While the traction on the head was thus in force the same side pull of 25 lbs. was made as before and the results noted. Two experiments of this sort were made. It was found that the spine without traction was displaced to the side nearly twice as far by a definite side pull as by the same amount of side pull when traction was being made.

A confirmatory experiment was made on a boy of fifteen, using 75 lbs. of head traction and 15 lbs. of side pull. The result was the same.

The conclusion is that extension of the spine by an upward pull on the head is a corrective force in scoliosis but that much more force is required to accomplish a certain amount of side correction than is the case if the force is applied from the side.

The other conclusion is that to secure the maximum of side displacement from a given amount of side pressure the spine must be slack and not stretched in its length.

Finally, it may be said that to obtain growth in a desirable position, *overcorrection* of the existing deformity should be obtained where possible. It is obvious that to obtain this the use of great force will be necessary.

The treatment of severe scoliosis by plaster jackets applied in a corrected position is not new. But the force used has been on the whole mild and generally applied to the spine during suspension. Bradford and Brackett [18] described a frame in which the jacket was applied as the patient lay prone, but even here head traction was used. Hebel, Calot, Redard and others have also used the horizontal position.[19] Yet in 1898 Hoffa, the well-known German authority, wrote in his textbook, "Bei den Skoliosen dritten Stadiums lasst sich eine Besserung in der Contour des Rumpfes erzwingen, man kann ein weiteres Fortschreiten der Verkrummung bis zum Aeussersten verlusten und die Interkostal Neuralgien beseitigen." [20]

The whole question was given a new impetus by Calot's work on the forcible correction of the deformity in Pott's disease published in 1896, and a few articles dealing with the subject have appeared since then.[21] The later tendency has been toward the use of much greater force than was previously employed.

The most noteworthy advance in the forcible corrective treatment of scoliosis has been made by Wullstein, who has applied the above-mentioned principles with force and precision and who publishes photographs showing marked improvement in patients. His method is to forcibly extend the head while the patient's pelvis is strapped to a seat which can be tilted to make the pelvis oblique and which also can be rotated to change the relation of the pelvis to the spine. Lateral pressure is made by pads running in horizontally from the sides of the apparatus. By a combined motion of the seat and adjustable pads any degree of twist of the spine upon the pelvis may be produced. Wullstein uses an appalling amount of force in his traction, applying up to 250 lbs. of pull, and he applies a plaster jacket while the patient is thus stretched and pushed into a corrected position. This jacket embraces, as must all such jackets to be wholly efficient, the chest, shoulders and head.

I do not personally believe that Wullstein's attempt to correct rotation by a torsion of the whole spine is based upon correct principles nor that torsion can be so corrected (for reasons given in another paper),[22] but with this unimportant exception the method is progressive, rational and effective.

The amount of force required, however, is excessive, as must be the case where force is not

economically applied. He is attempting to straighten the bent stick by pulling the two ends apart, and when a great amount of force has thus been expended in stretching the spine, lateral pressure is applied, when it also must be pushed to an extreme on account of the stretching of the spine in its length.

I had been working at the same problem in the attempt to utilize the force in its most efficient way by making side pressure, that is, attempting to straighten the bent stick by bending it over something instead of trying to pull apart its ends, and published my first results in 1901.[23]

More extended experience has confirmed me in the belief that even in adults much correction may be accomplished by the use of properly directed side force and that, at least in growing persons, retention in the corrected position causes diminution of the bony deformity.

The criticism that such correction is not likely to be permanent at once presents itself. The method in its later application is too new to enable one to make the statement that such results have proved to be permanent in cases observed, consequently one must consider the probabilities on general grounds. The grounds that lead one to suppose that retention of the corrected spine in a corrected position over a sufficient period will lead to a change in the shape of the bones of the vertebral column and to a permanently improved position are as follows:

(1) Clubfoot may be cured by a similar proceeding.

(2) The bones of the feet of Chinese women of rank are seriously misshapen by retention in an unnatural position.[24]

(3) Wullstein produced bony changes in dogs by a few months of abnormal position.

(4) W. Arbuthnot Lane has demonstrated that the carrying of heavy loads by laborers will produce changes in the bony skeleton and that the changes vary according to the habitual position of the load,[25] the bones subject to the greatest pressure undergoing changes in shape.

(5) The fact that bone under pressure changes shape after growth has been reached is shown in the fact that scar tissue pressing on bone will cause a change in shape,[26] *e. g.*, on the chin.

(6) Pressure of tumors or aneurism will cause absorption of bone.

These facts all point to the conclusion that bone alters its shape under changed conditions of pressure, and that although this would be more marked during growth, the phenomenon is not unknown in adult life.

For a permanent cure, therefore, retention for some time in the corrected position is essential.

My attempt, therefore, has been to exercise as much side pressure as can be borne upon the slack spine (that is, the spine not stretched in its length). I have done this in the hope of stretching muscles and ligaments and thus in time changing the relation of vertebræ misshapen by pressure. Having thus secured an improved position I have endeavored to retain it by portative apparatus and gymnastic exercises.

No preliminary treatment in the way of stretching and forcibly manipulating the spine has been used in preparing patients for the application of the jacket. Both Wullstein and Schauz use the corrective apparatus finally to be used for the application of the jacket for several days to loosen up the spine and secure an improved position when the final application of force is made.

To secure the slack condition of the spine correction has been applied in the prone position. To diminish as far as possible the physiological curves (especially the lumbar) during the correction the legs have been flexed and allowed to hang down. In the earlier corrections the patient lay face downward on two straps of webbing tightly stretched from one end of a gas-pipe frame to the other, the legs hanging down and the feet resting on the floor or on a box. Side pressure was then made by bandages running from the side of the frame around the convexity of the lateral curves and back to the side of the frame. In this way satisfactory results were obtained, which will be shown later in the article.

But there are obvious objections to this method which aims only at correction of the lateral deformity and which does not attack the rotation.

It has been long recognized[27] that corrective retention jackets often increase the rotation by diminishing the lateral curve. It has been pointed out by the writer that in fixed curves corrective side pressure results in increase of the rotation and corrective forward pressure to diminish the rotation results in increase of the lateral deformity. The method of the writer was therefore open to the objection that it might increase the rotation permanently while improving the lateral deviation. Such would not seem to be the case in the photographs shown, but the method was obviously incomplete, theoretically in any event.

The writer's aim in devising a corrective apparatus was to keep the two corrective elements separate, that is, to correct the side curve and then by a forward or back pressure to correct the rotation while the side correction was maintained. In this way neither of the two need be corrected at the expense of the other, but the maximum of one having been obtained and held the maximum of the other was added. Either could be used alone and the relative amounts of each regulated.

Oblique pressure, which aims at securing correction of both side deviation and rotation by the same force, is less accurate and can be better used when split into its two components. Most if not all of previous apparatus has aimed at oblique corrective pressure.

The problem of the application of plaster jackets on this plan having thus presented itself was worked out mechanically by Dr. Z. B. Adams of the Boston City Hospital, at the time

assistant in the lateral curvature clinic at the Children's Hospital.

The apparatus constructed by him consisted of a heavy gas-pipe frame three by four feet. The patient lies face downward on two webbing strips running from end to end of the frame with the legs flexed. Near the bottom of the frame is an adjustable crossbar bent to fit into the flexure between the thigh and the pelvis on which the patient rests the lower part of the body. Sliding on this bar are two arms, which slide in and clamp down on the buttocks, holding the pelvis steady on the crossbar. This bar is movable from side to side in order to induce or correct curvature in the lumbar region when necessary. There are three vertical transverse rings two feet in diameter fastened to pieces on the sides of the frame so that they can be moved to any desired point along the frame. These rings are also movable from side to side and by an independent movement they can also be rotated through a half circle. Any one of these movements can be checked at any point by turning a screw. The shoulders are held by a pair of axillary straps fastened together by a strap across the chest in front. These straps are suspended from the ring nearest to the top of the frame and can be made to hold the shoulders in any desired degree of twist by a rotation of the ring.

Each ring is provided with two long screws at the two poles of the ring. These screws are adjustable upon the ring and can be set at any desired angle to it. By rotating the ring and adjusting the angle of the screws they can be made to screw down or up upon any part of the back or chest.

For the application of the jacket the patient lies on the face on the two webbing strips, the lower part of the trunk resting on the cross rod and the bars clamping the buttocks; the feet rest on the floor and the arms are extended above the head. The rings are then adjusted at the two levels where it is desired to make correction, generally in the dorso-lumbar and the dorsal regions. For side correction a bandage is fastened to one side of the ring, carried around the patient's side over a heavy pad of felt and back to the ring. The same is done to the other ring at the other level where side correction is desired, while the top ring controls the shoulders. The rings are then pulled to one side, the bandages around the patient tighten and any endurable degree of side correction obtained.

When the side correction is made the ring is rotated till the screws are opposite the points where it is desired to correct rotation. They are then screwed down on to the patient, their points being protected by sheet-iron pads two by three inches, which are covered with heavy felt. These pads are incorporated in the jacket.

The shoulders are controlled by the axillary pads attached to the upper ring along with screw pressure up or down as desired. In the correction each level is separately attacked.

The pelvis is always held firmly and cannot rotate. If two curves exist, correction of the lower curve is first made — first, side correction, then rotation correction. Next, the dorsal curve is attacked and corrected to square with the pelvis. The shoulders are finally inspected, pulled to one side if necessary and twisted into a parallel position to the pelvis. A plaster jacket is applied to the patient held in this way. It is easy to see that the method is perfectly definite and that the amount of force at the operator's disposal is very great.

Separate correction in two planes may be made at any level while the pelvis is firmly held and correction at one place may be made independently of correction at any other place and either side deviation or rotation or both may be corrected at each level.

In the third case in which the apparatus was used a child six years old with a very severe curve from infantile paralysis was corrected. The deformity yielded readily without much pain and almost wholly disappeared; a jacket was applied; ether was not used. The child showed signs of collapse in the night and the next morning was somewhat cyanotic and stupid although conscious, radial pulse was absent, the extremities were cold and bluish and the condition generally alarming. The jacket was split and the alarming signs disappeared.

In the cases in which this frame has been used it has seemed to have very great corrective power, and great power is needed if overcorrection is to be obtained, which, just as in club-foot is the desideratum.

Such corrective jackets are worn for a period of two or three weeks and changed once or twice, just so long as further correction seems obtainable by another jacket. In the earlier jackets good correction seemed to have been obtained in a week and that period was adopted, but that time seems on general grounds to be too short and the longer period has been substituted. The last corrective jacket when removed is used as a mold for a plaster torso and a leather or celluloid or other retentive corset constructed from it. This is worn day and night and only removed once a day for heavy corrective gymnastic work, which is pushed to the limit of the patient's capacity.

Such retentive apparatus, whatever it is, should aim at holding the patient in an over-corrected position or as near it as possible from the pelvis to the base of the skull.

It is not intended here to dwell on braces or corsets, but rather on the essentials of the method. A useful brace, however, for out-patient work is found in a leather corset stiffened by bayberry tallow with a window for pressure from a leather pad on the convexity, the point of counterpressure being offered by an iron bar and two pads, one over the pelvis and one in the axilla, on the other side of the jacket. It is essential that room be given on the side away from the pressure for the patient to be pulled over and this is arranged by cutting out part of the side of the jacket on the side of the concavity of the curve and pulling by straps on the

pad set in the window over the convexity. In my experience jackets may be gradually discontinued in all but the extreme paralytic cases after a period of perhaps two years.

With regard to the relative merits of the suspended and the prone position it may be said —

That suspension works on the whole spine and distributes itself and untwists the rotation while it straightens the lateral curve, but it is obviously not corrective enough by itself when pushed to its limit or Wullstein would not have to add to it side pressure. The chief objection to it is that it is an uneconomical application of corrective force and that pushed to the point of obtaining overcorrection it must reach an almost unendurable grade of pull.

In the prone position fainting is less likely, there is less discomfort, and far less force is required to obtain a definite amount of correction, because the force is more economically applied and the back can be inspected through the early part of the process.

Personally, I think it a great advantage to have the lumbar curve held by the jacket as flat as possible, as thereby I believe that a corrective extending force is exerted upon the dorsal curve.[28]

The claims of efficiency to be made for the apparatus may be repeated:

(1) The most economical use possible is made of the corrective force by applying it sideways and thus less force is required or the same amount of force will do more than in extension of the spine.

(2) The force is applied to the spine while slack and not made tense by extension.

(3) Side correction is made by one part of the appliance.

(4) Correction of rotation is made by another part of the appliance.

(5) The pelvis is held in a position which ensures some flattening of the lumbar curve, which in the upright position tends on account of the balance of the patient to bring about straightening of the dorsal curve.

(6) Finally, it may be said that general pathological considerations would seem to indicate that retention in the corrected position should induce changes in the shape and relations of the misshapen bones.

CASE I. Boy, thirteen years old in 1900. Severe infantile paralysis of one side of back and one leg, shortening of one leg of one and a half inches. Treatment for some years by braces and gymnastics. Forcible correction by four jackets in January, 1903. Since then retention in celluloid jacket, daily stretching in the prone position and hanging, with a few gymnastic exercises to develop the remaining muscles. A doctor who had given exercises in 1901 and previously and who examined the boy in December, 1903, wrote, "I found that he had gained considerably in muscular power. The back muscles were much stronger and the abdominal muscles had gained also."

CASE II. Eighteen years old in 1901. Severe infantile paralysis of one side of back and of leg; very rigid. Brace treatment for many years. Plaster correction jackets applied in 1901. Retention jacket and exercises since then. Gain in height since 1901, seven-eighths of an inch.

CASE III. Girl, eighteen years old, no previous treatment. Rigid scoliosis; no paralysis; four corrective jackets in July, 1903; since then exercises and retention corset.

HYDROTHERAPEUTIC PRESCRIPTIONS.

BY JOSEPH H. PRATT, A.M., M.D., BOSTON.

Physician to Out-Patients, Massachusetts General Hospital; Assistant in Theory and Practice of Physic, Harvard University.

DURING the past decade rational hydrotherapy has made great advances, particularly in Germany and Austria. The position hydrotherapy occupies to-day in the treatment of disease is largely due to the physiological and clinical investigations of Winternitz of Vienna, which placed the empirical water treatments on a scientific foundation. We are now able to predict, as von Hoesslin [1] says, the action of a definite hydrotherapeutic procedure in a given case with as much certainty as we can that of morphine and digitalis.

Dr. S. Solis Cohen, in his "System of Physiologic Therapeutics," suggests that "there should be maintained in every city an establishment to which any physician might refer his patients with a definite hydriatic prescription, just as he can now send them to the apothecary with a definite pharmaceutic prescription." A number of Boston physicians, feeling the need of such an establishment, met together at the suggestion of Dr. J. J. Putnam on Oct. 13, 1903, to consider the advisability of maintaining an institution for physical therapeutics "where pri-

[1] v. Hoesslin. Penzoldt u. Stintzing Handbuch der Therapie innerer Krankheiten, Jena, 1903, v, p. 110.

vate patients could be carefully treated and suitable researches carried on, and which should be under the supervision of a competent physician."

It was realized that unless such an institution was established facilities would be lacking in Boston for giving patients the benefit of the best methods of physiological therapeutics.

On motion of Dr. F. C. Shattuck it was voted to ask a committee composed of Drs. J. J. Putnam, E. G. Cutler and R. W. Lovett to propose a plan for organizing and maintaining a hydrotherapeutic establishment. The report of the committee was accepted and through its labors and the generosity of physicians and laymen a hydrotherapeutic institution owned and controlled by the medical profession was rendered possible.

Any surplus income is to be devoted to improving the establishment or adding new apparatus. The "Medical Baths," as it is called, was opened early in December, occupying quarters in the Farragut Building at the corner of Massachusetts Avenue and Boylston Street. There is a reception room, five small treatment and dressing rooms, a large treatment room and a douche room with a Baruch douche apparatus. The treatments are given by graduate male and female nurses well trained in hydrotherapeutic methods.

Many valuable hydriatic procedures can be carried out in the homes of patients very simply if a trained attendant is available, but of all forms of water treatment, the douche is the most powerful and the most varied in its action. The douche treatment requires elaborate apparatus and skilled operators. It differs from other hydrotherapeutic measures in its mechanical effect, which promotes reaction and increases stimulation. Pressure and temperature can be perfectly controlled by means of Baruch's table, and hydriatic prescriptions exactly followed.

In hydrotherapy precision of method is essential to success. The effort has been made in the following pages to present the modes of treatment which experience and experiment have shown to be the best. Only the institution-treatment of chronic disease is considered. It is of course understood that these prescriptions must frequently be modified to meet individual needs. The reaction of the patient is the usual guide to such modification.

In all chronic diseases, but especially in diabetes, chlorosis and neurasthenia, the hydriatic treatment should be considered only as a part of the whole management of the case. If this is remembered the treatment will succeed in cases where it would otherwise fail.

Chlorosis and other forms of anemia. The value of hydrotherapy in chlorosis has only recently been recognized. The treatment should begin with mild measures. In debilitated individuals and all unaccustomed to cold bathing it is well to begin with the hot pack followed by the wet mitt friction (Prescription 1). When cutaneous lesions are present the cold towel rub should be used (Prescription 2).

As soon as the patient's skin becomes accustomed to cold water the wet sheet rub may be substituted for the wet mitt friction. This is the "*Abreibungen und Abklatschungen*" of the Germans (Prescription 3). And when this is well borne, the half-bath may be used (Prescription 4). As soon as the feeble patient by these moderate graduated measures has been trained to react well the stronger and more effective douche treatment is indicated (Prescriptions 5, 7). More robust patients and those accustomed to cold water can dispense with the milder applications and begin with the tonic douche.

v. Noorden makes use of the carbon dioxide bath in chlorosis (Prescription 6). In fact, he thinks it indicated in almost all cases. Sweat baths have been employed recently in chlorosis by Hegglin, Paul Schmidt, Dehio and Romberg in Curschmann's private practice (Prescription 8).

Chronic arthritis. Sweating procedures when there is no cardiac complication (Prescription 9). Unless there is a tendency to acute exacerbations it is well to follow the hot bath with a stimulating douche (Prescription 10). Local hot-air or electric-light baths are frequently beneficial (Prescriptions 11, 12).

Bier begins the course of treatment with the hot-air bath and later employs congestion-hyperemia (Bier's "*Stauungs-hyperæmie*," Prescription 13). Schuller and many others recommend the Scotch and the alternating douche (Prescription 14).

Douche-massage has been much used at Aix-les-Bains for a long time, and the method has quite recently been recommended by v. Leyden, Beissel and Machzun (Prescription 15).

Chronic muscular rheumatism. The procedures enumerated above under chronic arthritis are useful, especially short hot-air baths and the Scotch douche.

Sciatica and other forms of neuralgia. Vapor bath followed by hot pack (Prescription 16). Scotch or alternate douche to painful areas (Prescription 14).

Organic disease of the spinal cord, especially tabes. Hydriatic procedures are recommended by Erb, Senator, v. Strumpell, Stintzing, Matthes and others. Cold douches as a rule are poorly borne. The carbon dioxide baths hold the first place, especially in tabes, except when irritation phenomena exist (Prescription 6).

Exophthalmic goiter. Carbon dioxide baths (Prescription 6).

Chronic pleurisy. Wet sheet rubs, half baths and douches to the affected side are recommended by Fodor and Matthes (Prescriptions, 3, 4, 14).

Pulmonary tuberculosis. Hydrotherapy is a valuable adjunct to fresh air, good food and rest. With debilitated, poorly nourished individuals the hot pack followed by the wet mitt friction is recommended (Prescription 1). Other tonic procedures can be used to advantage (Prescriptions 3, 4, 5, 19).

Cardiac insufficiency. Hot baths weaken the heart, cold baths strengthen it. Carbon dioxide baths are of the greatest service. Benecke and August Schott were the first to show their specific action on the heart. They are indicated in cases with slight disturbances of compensation. Severe angina pectoris and advanced arteriosclerosis are contraindications. The baths should be administered by a physician or experienced nurse only. If the bath is of proper strength elevation of blood pressure occurs, associated usually with slowing of the pulse. Repeatedly we have demonstrated that the left border of the heart was 1 cm. nearer the midsternum after a bath. It is our custom to measure the blood pressure with the Riva-Rocci sphygmomanometer before and after each bath. Baths too strong for the heart overtax and injure it. If too weak there is no elevation in blood pressure and no diminution in the width of cardiac dulness (Prescription 18). A treatment consists usually of 25 to 30 baths, but the duration depends naturally upon the patient's condition. A course of less than 20 baths will not effect permanent good (Romberg).

The value of the baths is enhanced by combining with them the therapeutic exercises. As T. Schott has well said, "Movements without design weaken the heart; movements with design, on the contrary, strengthen the heart."

Cardiac neuroses. See neurasthenia.

Chronic gastritis, nervous dyspepsia, enteroptosis and *motor insufficiency of the stomach.* The wet sheet rub, cool half-baths and tonic douches have an invigorating influence and improve the appetite. Begin with a mild treatment such as indicated in Prescription 3. After a few days the skin will become used to the cold applications and then the douche should be employed (Prescriptions 5, 9). When there is epigastric pain or distress the Scotch or alternate douche to the abdomen is helpful (Prescriptions 14, 21). For enteroptosis, Boas recommends strong jet douches for the tonic influence they exert on the abdominal muscles (Prescription 20).

Constipation. Nothnagel advocates cold douches, but most authorities prefer the alternate douche (Prescription 22).

Diarrhea. General hydriatic procedures are used to improve the general condition (Prescriptions 1, 3, 4, 5, 19). v. Jaksch has recently highly lauded the cold sitz bath in chronic diarrhea, even when the condition is the result of serious disease of the intestine. Winternitz recommends that the cold sitz bath should be preceded by a wet sheet rub (Prescription 23).

Hemorrhoids. The cold ascending douche is of service. Its use can be combined with a general tonic treatment (Prescription 24).

Hypertrophy of the prostate. Prescription 24.

Neurasthenia. A stimulating treatment with the cold douche is of great value in many cases. If the patient is weak mild measures should be used at first, until by graduated procedures the skin becomes accustomed to cold water. Begin with the hot pack and wet mitt friction (Prescription 1) and then after a few days the wet sheet rub can be used instead (Prescription 3). Later the half bath (Prescription 4). In most cases by the end of ten days the douche can be used with advantage. At first the pressure should be low and the douche of very short duration. The skin should be well heated before any cold application. Well nourished individuals, especially men, will react well to the circular and jet douche at the beginning of the treatment and with them some or all the milder procedures may be omitted (Prescriptions 5, 25). The procedure indicated in Prescription 5 is the milder treatment, and is used chiefly with women. The best results with any given number of treatments are obtained when the treatment is repeated daily. Baruch advocates the following mode of procedure: Prescription 26 one week; Prescription 27 for the second week, Prescription 28 for the third week. For the type of neurasthenia with excitation, Beni-Bardi recommends the neutral douche. This has a sedative effect (Prescription 29). The Scotch douche to the back is indicated in neurasthenic spine (Prescription 14). The Scotch or alternate douche applied to localized painful areas may be helpful. The Scotch douche to the legs is useful in some forms of persistent headache (Prescription 30).

Hysteria. Excitable type (Prescription 31). Depressed type (Prescriptions 30, 32).

Chorea. To improve the general condition v. Strumpell recommends the wet sheet rub and short cool douches (Prescriptions 3, 19). Gowers uses sweating procedures (Prescriptions 8, 9, 10).

Chronic nephritis. Moderate sweating baths are of great service in keeping the skin active and healthy, and are also used for reducing edema and combating the milder symptoms of chronic uremia,—headache, mental torpor and bodily lassitude, anorexia, etc. They should be repeated two or three times a week. After a hot bath a salt glow followed by a hot douche is refreshing. Cold baths or douches are harmful in nephritis (Prescription 3). v. Leube and more recently Strauss have sounded a warning against too energetic sweating procedures in nephritis. The hot full bath is now used quite extensively in place of the sweat bath in the treatment of nephritis (Prescription 34).

In treating chronic interstitial nephritis with signs of cardiac failure the carbon-dioxide baths have been used with success by Baur and Matthes. The temperature of the bath should not be lower than 86 (Prescription 18).

Obesity. As F. A. Hoffmann says, no obesity treatment is complete without hydriatic procedures (Prescription 35).

Diabetes. Naunyn, v. Mering and v. Noorden recognize the importance of hydrotherapeutic aids in the diatetic treatment of this disease. Tonic measures increase metabolism, invigorate the patient and improve the condition of the skin (Prescriptions 1, 3, 4, 5, 25). v. Leyden. Handbuch der Ernahrungstherapie, I, p. 554. Leipsic, 1897.

PRESCRIPTIONS.

(1) Hot pack until skin is warm and cutaneous vessels dilated. Wet mitt friction, using water at 60° F. Repeat daily, reducing temperature of water 2° each treatment until 40° is reached. — *Kellogg.*

(2) Hot pack until skin is warm. Cold towel rub; temperature of water 60°. Repeat daily, lowering temperature of water 1° each treatment till 40° is reached. — *Kellogg.*

(3) Hot-air bath nearly to point of perspiration. Wet sheet rub; temperature of water 70°. Repeat daily, lowering temperature of water 1° each day until 60° is reached.

(4) Hot-air bath to point of perspiration. Half bath; temperature of water 70°; duration 1 minute. Repeat daily, lowering temperature gradually to 60° and increasing length of bath to 3 minutes.

(5) Hot-air bath to point of perspiration. Circular douche 105°–110°–90°, 2 minutes. Fan and jet douche to entire body 90°–80°, pressure 10 lbs., 1 minute. Lower minimum temperature 2°, and increase pressure 2 lbs. each treatment until a temperature of 60° and a pressure of 30 lbs. are used.

(6) Carbon-dioxide bath, 300 gm. HCl, 300 gm. Na_2CO_3; duration 10 minutes. Repeat three to six times weekly. Increase strength gradually to 500 gm. of acid and salt and duration to 15 minutes.

(7) Hot-air bath to perspiration. Circular douche 95°–80°, 30 seconds. Spray douche, 70°, 30 lbs., 5 seconds. General massage 10 minutes. Reduce temperature of spray douche 1° daily. — *Baruch.*

(8) Vapor bath; temperature 120°; ½ hour. Friction with warm dry towels. Rest in bed 1 hour. — *Nonne-Dehio.*

(9) Hot-air or vapor bath, 15–25 minutes, followed by dry pack 30 minutes. Rest in bed 1 hour. — *Matthes.*

(10) Hot-air or vapor bath, 15–25 minutes. Circular douche, 105°–110°–90°, 2 minutes. Jet and fan douche, 90°–85°, 1 minute, pressure 10 lbs. Repeat two or three times weekly, increasing pressure 2 lbs. and reducing terminal temperature 2° each treatment until pressure of 30 lbs. and temperature of 60° are reached.

(11) Local hot-air bath to affected joint, temperature 90° C., 1 hour. Spray douche 70°, 15 lbs. pressure, 10 seconds. Repeat daily, increasing temperature of bath 2° daily until temperature of 130° is reached.

(12) Local electric light bath, 15 minutes. Spray douche 70°, 15 lbs. pressure, 10 seconds. Repeat daily, increasing duration of electric light bath 2 minutes until length of bath is 40 minutes.

(13) Congestion hyperemia to affected joints, 1 hour. Repeat daily. — *Bier.*

(14) General hot-air bath to point of perspiration. Circular douche 105°–110°–90°, 2 minutes. Scotch or alternate jet douche to affected part or painful areas. Repeat daily.

(15) Massage and douche to affected joints, temperature of douche 92°–100°, duration 10 minutes. Circular douche 98°–110°, 2 minutes. Fan and jet douche to entire body, temperature 70°, pressure 15 lbs., duration 10 seconds.

(16) Vapor bath, 120°, 10 minutes. Scotch or alternating douche to painful parts. Hot pack 30 minutes. Rest in bed 1 hour. Repeat thrice weekly.

(17) Hot-air bath to point of perspiration. Circular douche 105°–90°, 2 minutes. Rain douche 86°–80°, 40 seconds, pressure 10 lbs. Oil rub. Reduce final temperature of rain douche 1° and increase pressure 1 lb. until temperature of 60° and pressure of 20 lbs. are reached.

(18) Carbon-dioxide bath, Na_2CO_3, 100 gm., HCl, 100 gm.; temperature 95°; duration 7 minutes. Content of CO_2 and duration to be increased and temperature lowered until duration of 20 minutes, temperature of 80° are reached and 1000 gm. of acid and salt employed. For first two weeks take baths three times a week, later every day. — *Romberg.*

(19) Hot-air bath to point of perspiration. Circular douche 105°–110°–100°, 2 minutes. Spray and jet douche to entire body, pressure 15 lbs., 70°, 20 seconds. Repeat daily, raising pressure 2 lbs., and reducing temperature of cold douche 2° each treatment until pressure of 35 lbs. and temperature of 60° are reached.

(20) Hot-air bath to perspiration. Circular douche 105°–95°, 2 minutes. Jet douche to abdomen 75°, 30 seconds. Spray douche to entire body, 75°, 10 seconds, pressure 12 lbs. Abdominal massage. Repeat daily, increasing pressure 1 lb. and lowering temperature 1° each application until 25 lbs. and 60° are reached.

(21) Hot-air bath to perspiration. Circular douche 105°–95°, 1 minute. Jet douche to abdomen, 10 lbs., 86° raised gradually to 120°, 15–10 minutes. Fan douche to abdomen, then to dorsal region, 13 lbs., 60°, 15 seconds. General jet douche, 70°, 5 seconds. Repeat daily for gastralgia. — *Beni-Barde.*

(22) Hot-air bath almost to perspiration. Circular douche 105°–95°, 1 minute. Small jet douche to course of colon, alternate 60° and 115°, 15 seconds each, pressure 15 lbs., 1–2 minutes. Fan douche to chest and back 75°, 10 seconds. Repeat daily for constipation, increasing pressure 2 lbs. each treatment until 30 lbs. are used.

(23) Hot-air bath until cutaneous vessels are dilated. Wet sheet rub. Sitz bath, temperature 70°, 10 minutes. Simultaneous hot foot bath, temperature 110°. Repeat daily, increasing duration gradually to 20 minutes and lowering temperature to 50°.

(24) Hot-air bath to perspiration. Circular douche 105°–95°, 1 minute. Ascending douche 60°–70°, 2–3 minutes, 5–10 lbs. pressure. Rain douche 105°, 30 seconds. Fan douche to entire body, 10 seconds, 15 lbs., 70°.

(25) Hot-air bath to point of perspiration. Circular douche 105°–90°, 2 minutes. Jet and fan douche 90°–80°, 15 lbs., 1 minute. Jet douche to spine 75°, 15 seconds. Lower minimum temperature 2° and increase pressure 1 lb. each application until pressure of 35 lbs. and temperature of 50° are reached.

(26) Hot-air bath until cutaneous vessels are dilated. Remove before perspiration begins. Circular douche 95°–85°, ½–1 minute. General fan douche 80°, 20 lbs., 10–20 seconds. Dry rapidly. Walk in open air, until somewhat fatigued. Repeat daily, reducing minimum temperature 1° each treatment. Once during week allow patient to perspire 5 minutes in cabinet. — *Baruch.*

(27) Hot-air bath almost to point of perspiration. Circular douche 95°–85°, ½–1 minute. Fan douche to back, 75°, 20 lbs., 5 seconds. General fan douche 78°, 30 lbs., 15 seconds. After several days substitute jet douche for fan douche to back, lower temperature of general fan douche 1° daily. — *Baruch.*

(28) Hot-air bath to beginning perspiration. Circular douche 25 lbs., 95°–80°, 1 minute. Jet douche to back, 30 lbs., 75°, 5 seconds, daily reduced 1°. Friction. Walk in open air. — *Baruch.*

(29) Hot-air bath to beginning perspiration. Circular douche 10 lbs., 105°–92°, 3 minutes. General fan douche 10 lbs., 85°, 15 seconds. Walk slowly in open air. Repeat daily, increasing pressure and lowering temperature until 15 lbs. and 80° are reached.

(30) Hot-air bath to point of perspiration. Change

cold compresses to head frequently. Circular douche 100°–90°, 2 minutes. Scotch or alternate jet douche to legs and feet, 15 lbs. Repeat daily, increasing pressure 1 lb. each application until 30 lbs. are borne.

(31) Wet pack; temperature of water 60°–70°, 1 hour. Circular douche 85°, 20 lbs. pressure, 15 seconds. Repeat daily; once or twice weekly initial temperature of circular douche 90°, reduce quickly to 75°, followed by fan douche, 85°–65°, 20 lbs. pressure, 5 seconds. — *M. P. Jacobi and Baruch.*

(32) Hot-air bath to perspiration. Circular douche 25 lbs. pressure at 85°, 30 seconds. Spray douche 65°, 5 seconds. After a few applications, use jet douche to spine at end of treatment for 3 seconds, temperature 65°. Lower temperature of jet 2° daily until 50° is reached. If this is well borne pressure may be increased 2 lbs. daily until 30 lbs. are reached. — *Baruch.*

(33) Vapor bath 120°, 15 minutes. Ice bag to praecordia. Salt glow. Jet douche to entire body, 10 lbs., 110°, 30 seconds. Rub dry. Rest in bed 1–2 hours. Repeat two to four times weekly, increasing pressure until 30 lbs. are employed and gradually increasing length of vapor bath to 30 minutes.

(34) Hot full bath, 100° raised to 106°, 5 to 10 minutes. Salt glow. Fan or jet douche to entire body, 110°, 30 seconds. Massage to edematous portions. Rest 1–2 hours before dressing. Repeat two to four times weekly, increasing pressure until 30 lbs. are used.

(35) Hot-air bath, 40–60 minutes. Soap shampoo. Half bath; temperature 70°, 3–5 minutes. General jet douche, pressure 25 lbs., temperature 70°, 20 seconds. Dress quickly and walk until fatigued. Repeat daily, increasing duration of hot-air bath and lowering temperature of douche as condition of patient indicates.

AN ACCOUNT OF THE WORK, INCLUDING OBSTETRICAL TECHNIQUE, AT THE LYING-IN HOSPITAL OF THE CITY OF NEW YORK.[1]

BY CHARLES H. BRADLEY, M.D.

I HAVE been requested to outline for you the work done at the Lying-In Hospital of the City of New York. Understanding that this society is especially interested in medical education, I shall speak more of the obstetrical education of the student at this hospital, and for this reason will deal at length with the Outdoor Service.

History. — In 1799 a number of public-spirited citizens of New York petitioned the governor that they be incorporated as "The Society of the Lying-In Hospital of the City of New York," with the express purpose of finding homes and giving medical assistance to women in child-bed. To this worthy purpose the society owes its birth.

Thirteen years ago the Broome Street Dispensary and the society joined forces; an indoor service was added in 1895, the hospital standing on the site of the present one, which was opened Jan. 1, 1902. The building of this new hospital was made possible through the generosity of Mr. J. Pierpont Morgan and other citizens of New York. This description would be incomplete without recording the indomitable energy shown by Dr. James Markoe and other directors in supervising the construction and adding the many details that make this hospital a leading exponent of the science and art of obstetrics.

The Student. — The Lying-In Hospital is an institution the purpose of which is to teach obstetrics, quite as much as to conduct a work of charity. This purpose being fully recognized one cannot but believe that the student benefits thereby. The student resides in the main hospital during his term of service, — a restaurant being provided where he may obtain food at cost.

The service is three weeks in duration, and divided into two parts, that obtained in the hospital and that in the outdoor service. The first seven days are spent in the hospital, where he has demonstrated all normal and abnormal cases, makes rounds with the visiting physicians and house staff and receives instruction in the diagnosis and treatment of those abnormalities incident to the anti-, inter- and postpartum periods. Each afternoon he goes to the antipartum rooms, where all cases are examined applying for care in their homes during the labor. The house staff teach him the symptoms and signs of pregnancy, their importance and the treatment of any abnormality arising. Here he has an opportunity to practice the methods of sterilization of his hands for a vaginal examination. Thus by the end of seven days he has become familiar with the technique, incident to the care of a normal case of labor.

Before going to the outdoor service he receives instruction in the use of the contents of the "labor" and postpartum bags, the correct method of keeping the outdoor histories, of making postpartum calls and the asepsis and antisepsis employed.

Outdoor Service. — For the next seven days he is a junior on the outdoor service, the junior of the week before becoming a senior. He now accompanies one or other of the eight seniors on the labor cases, acting as assistant and being given abundant opportunity to examine all cases. In addition, he makes four to six postpartum calls daily; these, on account of the large area covered by the department, are assigned according to locality. Before being entrusted to make calls alone, he is taken by the

[1] Read at the Section for Obstetrics and Diseases of Women of the Suffolk District Medical Society, Nov. 25, 1903.

outdoor staff and taught the method of making postpartum examinations, the points to be noted and the treatment of any abnormality.

On his return to the hospital he reports any abnormality, which is entered opposite the patient's name, on a slate. He then writes the result of his examination on each patient's history, and signs it.

During the last seven days of his service he is a senior and rotates with eight other seniors in the care of the cases applying for treatment in the outdoor department.

To each case of labor he takes a full antipartum record of the case, covering:

Past History, special attention being paid to the gynecological and obstetrical portions.

External Examination, including heart, lungs, breasts, abdomen, uterus, child, external pelvimetry, height, weight, varicosities and edema.

Internal Examination, including measurements of outlet, diagonal conjugate, depth of symphysis, and calculation of true conjugate; the condition of perineum, vagina, cervix and uterus (bimanual).

While on a case of labor he is required to send to the hospital or its branch a report every two hours, stating the progress of the labor. Throughout the labor he keeps a miniature labor sheet, so that he has only to copy this on to a larger sheet on his return to the hospital. While he is attending a labor, he is visited by one of the staff on duty, the external and internal examination and any abnormality investigated. In all primiparæ he is further required to send a report when the os uteri is fully dilated, in order that one of the staff may reach the case, to instruct him regarding the perineal stage, and the methods used to prevent laceration. Thus the hospital holds the student responsible for his work: (*a*) By requiring his signature to each history, and postpartum visit. (*b*) By a report every two hours during a case of labor. (*c*) By having each labor case visited by the staff. (*d*) By noting the receipt of the call, departure and return of student by means of a time clock.

Outdoor History Room. — A room is set aside for the writing of the outdoor histories. Here each student has a clip containing the cases he visits. This room is in charge of one of the outdoor staff, who serve in turn, and are responsible for the accuracy of the records. Each labor case is examined, and all postpartum calls are investigated, so that any mistakes may be pointed out to the student while the case is fresh in his mind.

During his period of residence the student keeps the application number of each case he has demonstrated to him or delivers. This report is verified and signed before he leaves the hospital. At the termination of his service, if his work has proved satisfactory, he is awarded a certificate.

The Outdoor Staff. — The outdoor department attends about twenty-five hundred cases annually, and for their care the hospital employs one chief of staff (the house surgeon), nine staff men, a head nurse and about twelve nurses.

The staff are on duty twenty-four hours, the time being divided into two calls, 9 A.M. to 12 P.M., and 12 P.M. to 9 A.M. During each call the care of a certain portion of the service is assigned to him, as: Discharging of patients, antipartum examinations, ambulance work, visiting students on labor cases, care of abortions and those abnormalities noted by the student on his postpartum visits. Each abnormality is visited, treated, and a record of the case written in the "Abnormality Book," from which it is copied by the medical clerks into the patient's history.

The length of staff service is four months, ten weeks on the outdoor and six weeks on the indoor service, the appointments being made by competitive examination.

The Outdoor Department. — The outdoor department has a branch on Broome Street in the heart of the East Side where reports and labor calls are received and antipartum examinations made.

This office is open day and night, — duplicates of all student reports are kept both at the branch and the hospital (which is connected by private wire) so that the staff may follow the progress of the labor cases as he makes his rounds.

To give some idea of the population surrounding the Broome Street branch, I can do no better than to quote a few statistics from the New York state census of several years ago.

In the seven adjoining blocks there is a population of over twenty thousand, or nearly three thousand to the block, or five hundred thousand to the square mile. In New York the foreign born number 43% of the total population, but in the East Side 62.5%. Persons of foreign parentage in the whole city 80% and in the East Side 95%. Of these 54% are males, and 46% females. The percentage of families living in one room is 5.6% as compared with 12% in Philadelphia, or 13% in the tenement district of Baltimore.

Care of Postpartum Cases. — The care of the cases during the first three days postpartum devolves on the outdoor nurses.

When a nurse comes to the outdoor department she has been trained in the wards, nursery and operating room, where she acts as assistant to the indoor staff during the delivery of cases. Hence she is experienced in making postpartum calls, and her accuracy of observation can be relied on. The first two days the cases are visited twice daily, the third day once, a record of the visit being written in the history. On the fourth day the cases go to the students and are visited once daily, save on the sixth and eighth days, if normal, being discharged on the ninth day by the staff, and a record of the examination made on the history.

The work of the department is aided by the Ladies' Auxiliary, who keep a large supply of

materials to be sent to patients, and furnish scrubwomen to clean the rooms. A diet kitchen gives additional aid in assisting both patient and family during the puerperal period.

Labor. — The hospital depends on the patient to furnish a pail for waste water, a basin for hand washing and a supply of hot water.

The bag taken to the labor contains all the utensils necessary for the delivery of a normal case.

Two rooms are devoted as a laboratory to the outdoor department; here dressings are prepared, instruments sterilized and bags repacked. Nurses are at work day and night, so that all a student does, when called for a case of labor, is to apply at the laboratory for a bag.

Labor Bag. — The bags are made of leather, and lined with the same material; they are 17 inches long, 9 inches wide and 9 high, opening wide at the top, and when packed weigh 20 lbs. When a bag is returned from a case it is emptied of its contents, wiped out with a cloth soaked in corrosive and repacked with fresh materials. A list of the articles contained in the bag is herewith enumerated: 1 rubber pad, 1 douche bag, 3 agate basins, 2 vaginal douche tubes, 1 can sterile sponges, acetic acid, sterile green soap, alcohol, 1 can sterile vulva pads, 1 catheter, 1 bottle dry dressings, 1 bottle boric acid wipes, 1 nail brush and wooden point, silver nitrate 1%, comp. cathartic pills, 6 tapes for cord, 1 scissors, 1 pelvimeter, 1 eye dropper, scales, tape measure, oichloride tablets, sterile vaseline, miniature labor blank, birth certificate and reports.

The Rubber Pad is a modification of Kelly's pad, the seams being less numerous, and hence the durability increased. It is cleaned by scrubbing with soap and water, sterilized by scrubbing with 5% carbolic acid. By this method it lasts about a year. The pad is used in all labors, not only to protect the bed from discharges, but the patient from the infective bed clothing.

The Douche Bag is a four-quart fountain syringe, cleaned and sterilized in the same way, and lasts about six months.

The Agate Basins telescope one into the other, the larger are used for bichloride and hold about a pint. The shallow basin holds the scissors, tape, boric acid wipes and cord dressings, each in its container. The basins are sterilized by washing with sapolio and corrosive 1-1000.

The Douche Tubes are of glass, straight, with bulb ends. They are placed in a brass cylinder (brass having been found preferable to copper, as it can be bought as tubing and is seamless), with a perforated lid, and sterilized.

The Sterilizer used is the Bramhall-Deane, the contents being exposed to steam under 12½ lbs. pressure, for thirty minutes.

The Soft Rubber Catheters are carried in a jar with a screw cap.

The Tape for the cord is bobbin, one-fourth inch in width, and cut in 12 inch lengths; these are placed in a bottle with a screw cap.

The Dressing for the cord is dry gauze, cut in 2 inch squares, and packed in a 4 oz. salt mouth glass bottle.

The Wipes for mouth and eyes are of gauze, 2 inches square, and packed in a similar manner, in a saturated solution of boric acid. All the above articles are sterilized under 12½ lbs. pressure.

The Vulva Pads are made from cotton waste, cut in sections 4 inches square, and ½ inch thick; two of these strips rolled in gauze will make a pad 8 by 2 inches. They are packed in cylindrical copper cans, perforated at the ends, and sterilized.

Cotton Waste is packed in a larger can, sterilized and used for sponging during the labor.

Nail Brushes have wooden backs and bristles of wood fiber. They are sterilized in a small copper cylinder; with the brush is placed a wooden point for cleaning the nails.

The Scissors for cutting the cord are sterilized in a towel.

Delivery. — Normal cases are delivered on their own beds, a board being inserted under the mattress if obtainable, and the mattress covered with enamel cloth or newspapers. Over this is placed the rubber pad, the end draining into a pail.

Position of Patient. — The side position is insisted on during delivery, since it raises the patient's genitals from the bed, keeps the hands of the attendant from touching it and gives a better control of the head during the perineal stage, while more of the patient's legs and shoulders can be covered than in the dorsal position. The materials used during delivery are placed on a chair and used directly from their containers.

Whenever assistance is required, the hospital is notified either by telephone or report, and the staff takes a bag with him containing additional supplies.

Contents of Staff Labor Bag. — Perineorrhaphy set, packing set, 3 tubes gauze, sterile green soap, fluid ext. ergot, hypodermic set, 2 intrauterine douche nozzles, sterile towels, sterile brush, infusion set, chloroform and mask.

The Perineorrhaphy Set consists of thumb forceps, 2 volsella needle holders, uterine dressing forceps, and needles, sterilized in a towel. *The Gauze* is packed in glass tubes, each containing 12 yards, and sterilized. *The Intrauterine Nozzles* are packed, and sterilized as previously described. *Chloroform* is contained in a plain drop-bottle; the *Mask* is that of Esmarch. The suture material consists of plain, chromic and silkworm gut.

Sterilization of Hands. — (1) The nails must be short, all abrasions covered with collodion. (2) The hands are scrubbed for three minutes with green soap and hot water. (3) Rinsed in clean water, the nails being cleaned with the wooden point. (4) Scrubbed again with soap and hot water for two minutes. (5) Scrubbed in 1-2000 corrosive for three minutes.

The fingers are brought in contact with the

genitals wet with bichloride, no lubricant being used.

Preparation of a Normal Case. — A normal case receives no antipartum douche, the vaginal secretion rendering the vagina sterile, while antiseptic and mechanical treatment renders it more liable to laceration. Any case that has inflammation of vagina or bladder at time of antipartum examination receives appropriate treatment in the outdoor clinic.

For normal labor the only preparatory treatment is external. When a student reaches a case of labor his first duty is to cleanse the genitals in the following manner: (*a*) If the vulva hair is matted it is cut, otherwise not. (*b*) The external genitals, inside of thighs and abdomen, are scrubbed with soap and water, followed by corrosive 1–2000; this being repeated every six hours in prolonged labor.

The patient is delivered on her left side, as previously described, both legs being flexed, the right foot resting in the junction of left thigh and leg. The attendant having sterilized his hands passes the left in front of the patient's abdomen, between her thighs; with this hand he controls the advance of the head, leaving his right free to sponge or reinforce the left when necessary. As soon as the head is born, the patient is turned on her back, the delivery being completed in this position.

When the cord stops pulsating it is tied and cut, a vulva pad wrapped around umbilicus, and tied over the back, the child covered, and laid aside. In the meantime the eyes and mouth have been wiped with boric acid and 1% silver nitrate instilled into the eyes. Thirty minutes are allowed for the spontaneous separation of the placenta; if at the end of this time it has not done so, it is separated manually by the method of Credé.

The fundus uteri is held from the delivery of the child, until one hour following expulsion of the placenta. Following the expulsion of placenta the genitals are wiped off with corrosive, and a vaginal douche of the same antiseptic, 1–8000 administered, not so much as an antiseptic precaution as a prophylactic against uterine hemorrhage. A vulva pad is then applied, followed later by an abdominal binder.

The Child. — The child is thoroughly examined, both body and diameter of head measured, greased with sterile vaseline and later washed, the cord being dressed with materials before described.

Much has been written of late regarding the advisability of vaginal examinations during the progress of labor, but it seems necessary in conjunction with external palpation, in the instruction of the student. On the outdoor service 27,693 examinations were made on 5,109 patients in the first stage of labor, an average of five examinations to the patient; 22,627 in 5,843 cases, in the second stage, an average of four examinations, and in spite of this extensive use of material for instruction the mortality of all cases dying of sepsis was only 0.14%.

Operations on the Outdoor Service. — For a *perineorrhaphy* the patient is drawn to the edge of the bed or placed on a table; anesthetized or not as the operator prefers. The inside of the thighs and genitals are scrubbed with soap and water and washed with corrosive. Sterile towels are placed below and above each thigh, and the perineorrhaphy set laid on a chair near the bedside.

The same preparations may be used for packing, the gauze being held in glass tubes. When the cervix has been drawn down by a volsellum the gauze is introduced from its container into the uterus, the tube being held by an assistant, or in his absence between the knees of the operator.

For *intrauterine manipulations* gloves may be used, being easily carried in a glove case.

When more serious operative interference is necessary, the lightest room in the tenement is selected, a table covered with a blanket or comforter and the rubber pad placed at one end. The patient after being anesthetized is placed on the table, the legs being held by means of a canvas crutch. The vulva hair is shaved, the patient scrubbed with sterile green soap and water; then 5% lysol, followed by boiled water and 1–3000 corrosive. For curettage the vagina is scrubbed with soap, water, lysol and douched with corrosive. The legs are encased in sterile towels, abdomen and rubber pad being covered with the same materials. The preparation above described is the same for forceps, curettage or version.

In a case of curettage, if the uterus has been packed the gauze is removed, otherwise the cervix is dilated with the Godell-Ellinger dilators, a digital examination made, following which the uterus is gone over with the dull, followed by the sharp curette. A hot corrosive douche, 1–5000, usually controls the hemorrhage; if not, the uterus and vagina are packed with iodoform gauze, the vaginal portion beng removed in twenty-four and the uterine in forty-eight hours.

Cultures are taken from the vagina and uterus before curettage and these with the curettings are sent to the pathologist for examination, the findings being recorded on the history of the case.

The Uterine Culture Tubes consist of a large tube ten inches in length and one inch wide. Inside of this, and running its length, is a glass tube, the lower end of which is plugged with cotton, to which a string is attached; the upper end is contained in the cotton plugging the mouth of the test tube. Inside the inner tube is the brass wire with swab attached, the free end of wire extending outside tube about three inches, and with it the string attached to the plug.

The perineum is depressed by means of a speculum, the cervix thoroughly swabbed, and the inner glass tube and swab introduced into uterus; the plug is now drawn out by means of the string, the swab pushed up to the fundus, then redrawn into tube and out through the upper end.

Special bags are kept packed with the sterile materials and instruments necessary for forceps and curettage, and can be sent to a case on the shortest notice.

Symphysiotomy and Cæsarean section have been performed on the outdoor service, but at present cases needing these operations are sent to the hospital in the ambulance. At all severe operations a nurse and at least two of the staff are present.

I have here a pair of Tucker-McClain solid blade forceps, used almost exclusively in the Sloane Maternity, — their advantages, you doubtless know, are: Ease of application, less liability to lacerate the child and the perineum, owing to the narrowness of the shanks, while their opponents claim a greater liability to slip.

The time will only allow a mere outline of the work inside the hospital. The service is divided into three divisions, each under a director and having a separate staff. Each division occupies a floor of the hospital, which consists of two postpartum, an antipartum and septic wards, six private rooms, a reception room, examining room, crying and operating rooms. The house staff on each floor consists of a senior and junior. The clinical and pathological laboratories, solarium, amphitheater and kitchens are on the seventh floor. The hospital has its own electrical and printing plants. A statistical department consisting of a registrar, assistant registrar and clerk classify and file all labor cases, keeping a card index of the same; so that the statistics of the hospital are kept ready for publication.

Nurses. — The nurses come from the various hospitals of New York, Brooklyn and suburban cities, from the Massachusetts General, Boston, and Lakeside Hospital, Cleveland, Ohio. The course is three months, being a portion of their hospital training. Post-graduate courses are arranged for both physicians and nurses.

House Staff. — The staff come from the various medical schools of the United States and Canada, as many as ten different schools being represented at one time.

Such, gentlemen, is the Lying-In Hospital, an institution connected with no medical school, its students coming from all parts of the country.

It fills a need, having the only large outdoor service in New York City.

Its results cannot but be far reaching, and of great benefit both to the profession and the community at large.

Clinical Department.

TWO SIMPLE FORMULÆ FOR USE IN THE ARTIFICIAL FEEDING OF INFANTS.

BY I. STANLEY KAHN, BOSTON CITY HOSPITAL.

IN the artificial feeding of infants, various formulæ have been suggested for the preparation of "home modifications" or "laboratory milks," whose constituents should be present in proportions suitable to the age and development of the child in question. I should like to offer for consideration a simple formula which will give approximately the amount of food required in twenty-four hours by the average healthy infant at various ages.

This formula reads:

The 24 hour amount in ounces=

$$11 + 5\sqrt{\text{The age of the child in weeks}}$$

This square root need only be approximate, and if taken by mental arithmetic gives as satisfactory a final result as if time is spent for its exact mathematical solution. In tabular form below are given some of the amounts obtained by using the formula in this manner, showing how closely they correspond with those advised by various observers.

24-HOUR AMOUNT IN OUNCES.

Age of Child	Formula	Ladd	C'd Oppenheim[1]	Starr[2]	Holt[3]
Up to 1 week	10*				
1 week	16	10	10	12	10–15
2 weeks	18	15	15		15–30
3 "	20		20	17	
4 "	21	22½			22–32
5 "	22				
6 "	23	24			
8 "	25	26	25		24–36
10 "	27				
3 months	28	28	28		28–38
4 "	31	31½	29	32	
5 "	33	33	31½		
6 "	35	34½	33	36	33–42
7 "	37	37½	39		
8 "	39	42	42	40	
9 "	41	42	42		
10 "	43	42½	42½		37–45
11 "	44	43½	44		
12 "	46	45	45		

From a glance at this table, it will be noted that the formula amounts differ but little from those obtained by practical observation. When it is considered how much these observers differ amongst themselves, which is but natural when it is remembered that their results can at the best be only approximate, and that each individual case must be judged for itself, it will be seen that any errors in the case of the formula, if really actual, amounting at the most to 2 or 3 oz., do not obviate its usefulness. This is emphasized by the fact that every error of 2 or 3 oz. is distributed over a number of feedings, rendering the amount given in the individual feeding practically identical with the amounts usually assigned as correct, and may hence be disregarded without harm.

In addition to the above formula, a second gives, with sufficient accuracy, the number of feedings in twenty-four hours according to the age of the infant to be fed. This second formula reads:

The number of feedings in twenty-four hours=

$$11 - \sqrt{\text{The age of the child in weeks.}}$$

In making this calculation, in order to avoid fractions in the final result, the exact age in weeks should be replaced by the nearest number

* Obtained from the formula,— Amount=11+5 $\sqrt{\text{o.}}$

[1] Oppenheim: "Medical Diseases of Childhood," 1900, p. 88.

[2] Starr: "American Textbook of Diseases of Children," p. 24.

[3] Holt: "Infancy and Childhood," 1901, p. 178.

with an exact radical; thus, in a child of seven months, using $\sqrt{25}$ instead of $\sqrt{28}$. Below are seen the results given by this formula compared with those prescribed by the Ladd Card.

NO. OF FEEDINGS IN 24 HOURS.

Age of Child	Formula	Ladd Card
1 week	10	10
2 weeks	10	10
4 "	9	9
6 "	9	8
2 months	8	8
3 "	8	7
4 "	7	7
5 "	7	6
6 "	6	6
7 "	6	6
8 "	5	6
9 "	5	6
10 "	5	5
11 "	4	5
12 "	4	5

From the total amount and the number of feedings, the size of the individual feeding can be easily computed. These two formulæ thus give the working practitioner the means for obtaining quickly results essentially as accurate for all practical purposes as those given in the various tables and textbooks.

New Instrument.

A NEW NEEDLE HOLDER.

BY JOHN W. KEEFE, M.D., PROVIDENCE, R. I.,

Consulting Surgeon to the St. Joseph's Hospital; Attending Surgeon to the Rhode Island Hospital, Providence, R. I.

THE number of needle holders which from time to time have been devised is an evidence that none are satisfactory to the majority of surgeons.

The holder shown in the cut I trust may meet the requirements some surgeons are seeking. The handle is one that may be firmly and easily held, thus having the instrument under complete control. The ratchet may be operated by the thumb, downward and outward pressure releasing, downward and inward pressure securing, the grasp of the needle. The last notch in the ratchet should always be used, irrespective of the size of the needle, as the elasticity of the

steel in the upper blade will accommodate it to any size needle. The jaws of the instrument being narrow and pointed permit the use of the holder in small and deep localities. A little time should be devoted to studying and practicing the methods of holding and releasing the needle, so that one may be able to use the needle holder with facility. The instrument was made for me by George L. Claflin & Co., Providence, R. I.

Medical Progress.

REPORT ON THORACIC DISEASE.

BY J. W. BARTOL, M.D., BOSTON.

INFLUENCE OF DWELLING ON SPREAD OF TUBERCULOSIS.

ROMBERG and Haedicke[1] report the results of a careful investigation, based on statistics and personal observation, of the morbidity and mortality record of tuberculosis in Marburg since 1890 with especial reference to localization amongst certain classes or districts of the city.

An epitome of their findings is: (1) Taking the one-fifth of the population in poorest circumstances, phthisis is present in 4.7%, while in the remaining four-fifths in better standing, it is found in only 0.2%. (2) Thirty-four per cent of reported deaths from tuberculosis occurred in 2.6% of the 1,503 dwelling houses. Amongst the poorest quarters, however, 59.2% of all tubercular disease was located in 33.6% of the dwellings existing in the given quarters. (3) Situation, construction and number of dwellers do not serve to explain relative frequency of cases in certain buildings. Although multiplication of cases does not occur in dwellings kept clean and neat, on the other hand, slovenly conditions alone do not account for occurrence of numerous cases in one household. (4) General considerations lead to the conclusion that most cases can be referred to the influence of infection. (5) Most cases are the result of not a single but of repeated infection with tubercle bacilli. Existence of conditions favoring repeated infection in the dwellings of the poorer classes leads to multiplication of cases in certain households, and in this aspect makes tuberculosis a disease influenced by the dwelling and therefore to be combated, especially in the poorer quarters of a town.

HEMATOGENOUS MILIARY TUBERCULOSIS OF THE LUNGS.

Several points of interest are apparently cleared up by Sawada[2] in a study of cases of miliary tuberculosis in rabbits' lungs resulting from the injection of bacilli into either the peritoneal cavity, the carotid or the anterior chamber of the eye. Investigations were also made as to the age at which the pulmonary lymph nodes develop in both infants and young rabbits. The conclusions reached are: (1) Hematogenous tuberculosis of the lungs experimentally produced in rabbits follows the statement of Ribbert for similar condition in man, in always originating in the lymph nodes. (2) Tubercle bacilli circulating in the blood, unless occurring in clumps, will not be arrested in the broader capillaries of the alveoli, but will locate within the lung if they pass into the narrow

[1] Deut. Archiv. klin. Med., Bd. lxxvi.
[2] *Ibid.*, xlvii.

branches of these capillaries which surround the lymph nodes. (3) Noteworthy differences exist in the reaction to hematogenous infection of the lungs of full-grown and of young rabbits. These differences depend on the stage of development of the pulmonary lymph nodes which do not reach completion until some time after birth. (4) In man the lymph nodes apparently do not reach full development until the fifth to seventh year. Experimental evidence indicates that it is on account of the incomplete development of the lymph nodes in the lungs of the young that children below this age contract the pulmonary form of miliary tuberculosis less frequently than adults. When they do contract it, it is probably in consequence of the presence in the circulation of large numbers of very virulent bacilli.

TREATMENT BY TUBERCULIN.

In a delightful account by Trudeau of his thirty years' work at Saranac given as Henry Phipps Institute lecture [3] he incidentally reports the results with tuberculin from 1890 to 1901. In these years 143 cases were treated by the various forms as prepared by Koch, including TR. Of these 143 cases 58% are alive, 33% are dead and 9% are untraced. In comparison, of the 1,367 cases treated during the same time without tuberculin 38.9% are alive, 39.6% are dead and 21.4% are untraced. This leaves apparently a credit of 20% in favor of the tuberculin treatment, but since the value of such a deduction is impaired by the fact that the tuberculin cases were to a certain extent selected and possibly of somewhat more favorable type, a comparison is made of the incipient cases only, which during the same period were treated with and without tuberculin. Of such cases which received no tuberculin 61% are alive, while of the tuberculin treated cases 76.7% are still living. A small but definite balance is thus still left in favor of the treatment.

DILATATION OF THORACIC AORTA AS CAUSE OF EMPHYSEMA.

Golubow [4] calls attention to the importance in all cases of emphysema of unexplained origin, especially in the elderly or those of syphilitic taint, of looking very carefully for aneurism or dilatation of the arch. Cases are detailed in which dilatation apparently led to a well-marked emphysematous condition and the causal relationship is explained on the basis of a reflex persistent cough set up by pressure on the vagus with emphysema as a result.

INTERCOSTAL PHONATION AND LITTEN'S PHENOMENON.

Abrams [5] records his experience with intercostal phonation (a diagnostic phenomenon first described by Stiller and consisting in the presence or absence of transmitted vibrations in the intercostal spaces when short words are spoken by the patient) as leading to the conclusion that, while it is often useful in determining the boundary between the lung and the liver or spleen, and in recognizing the existence of a pleural effusion or differentiating the same from pulmonary infiltration or tumor, the limitations likely to interfere with its demonstration are sufficient to prevent its attaining great value.

The study of the phrenic shadows, on the other hand, he finds of constant value, and from the fact that in many cases it furnishes a reliable substitute for the x-ray it is to be commended as a routine practice. In executing the manouvre he finds it not necessary to carry out the original directions for placing patient and observer but advocates (after skill in recognizing the shadow has been gained in the conventional way) placing the patient with back to window in diffuse light with arms raised and body inclined slightly backward, while the observer sits a few steps away with his back also to the window. In this way the shadow on both sides may be seen at the same time. The picture may be intensified by coloring yellow the skin over the given area, or by drawing taut a fold of skin in the vicinity.

CYTO-DIAGNOSIS.

The value of the different cells as indicators of the underlying process in pleuritis and other serous accumulations continues to be investigated by various observers with varying estimates. Kelty and Torday [6] give a review of reported progress of other observers and, as a result of study of 42 cases of their own, state several specific findings and the following general conclusions: Cyto-diagnosis is of great importance and practical worth in the discrimination of primary pleuritis in its early stage. A high-grade lymphocytosis in a case beginning with acute symptoms proves a tubercular origin. Lymphocytes may occur in pleural effusions of other origin in later stages, but in such cases other formed element and clinical observations serve as sufficient discriminating factors. The opinion already current that in later stages of acute cases not tubercular, lymphocytes are present in large numbers and indicate the chronic character of the process, is correct.

AUTOLYSIS IN LOBAR AND UNRESOLVED PNEUMONIA.

Among the alterations in structure and consistence, presumably autolytic in nature, Flexner [7] would include those occurring in acute yellow atrophy, Zenker's degeneration, the softening of infarcted areas and in malignant tumors. Turning to the lung, he says that, while in croupous pneumonia autolytic action is plainly an important factor in resolution, in caseous pneumonia autolysis begins probably only when certain bacteria invade the necrotic areas. Reasoning from the probable fact that in many pathological conditions the leucocyte is the essential agent in bringing about absorption, the conclusion seems justified that an explanation of

[3] Med. News, Oct. 24.
[4] Deut. Med. Wchnschr., Oct. 1.

[6] Deut. Archiv. klin. Med., Bd. lxxvii.
[7] Univ. Penn. Med. Bull., July-August.

the facility of resolution in croupous pneumonia and the difficulty of the same process in caseous, lies largely in the relative absence of leucocytes in the tuberculous process and their presence in enormous numbers in the acute inflammatory condition. Based upon the assumption, broadly stated, that exudates and necrotic tissue are removed by absorption or organization (both of which processes may be included under autolysis) and the experimental fact that autolysis takes place quickly and perfectly in gray hepatization but slowly and imperfectly in red hepatization and in cases of unresolved pneumonia, the conclusion is drawn that while autolysis after death is a mark of the tendency during life for the exudate to become absorbed (abundance of leucocytes), the absence of autolysis in unresolved pneumonia is equally an indication of the fate of the exudate during life to undergo organization. The fact being that the exudate in unresolved pneumonia is fibrinous rather than cellular and many of the alveoli are filled with dense hyalin fibrinous masses, the view seems a reasonable one that unresolved pneumonia is an acute lobar pneumonia in which the inflammatory exudate, either because of some disproportion between the leucocytes and other constituents or other cause as yet unknown, failing to autolyze perfectly, cannot be absorbed, and hence undergoes organization.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

Meeting Dec. 21, 1903, Dr. W. T. Councilman in the chair.

Dr. R. W. Lovett read a paper on

FORCIBLE CORRECTION IN LATERAL CURVATURE OF THE SPINE.

Dr. E. H. Bradford: The orthopedic surgeons of this community are indebted to Dr. Lovett for this paper and for the energetic investigation which he has been conducting on the subject of lateral curvature. As is well known this subject in surgery has been neglected much more than its importance deserves, and until comparatively recently the treatment of this common deformity has been placed largely in the hands of gymnasts and massage manipulators. Even the pathology was not well understood and methods of treatment were developed and practiced, although based upon faulty pathology, to the discomfort of many patients and with but little benefit to those who were obliged to undergo a long-continued treatment. One of the most striking instances of surgical error I had an opportunity to observe not many years ago in one of the English hospitals where a child was shown, at one of the clinics, who had been treated recumbent in bed for two years on a spinal couch for lateral curvature which, if left alone, would have been but little if at all worse than was the condition at the end of this long period robbed from the child's girlhood. Fortunately this former condition of pathological ignorance has been supplanted by more accurate knowledge of the nature of this deformity, and as the result of better knowledge of the subject more rational theories of treatment have been adopted and are now in vogue.

It is important to distinguish between cases of true scoliosis and simply faulty attitudes owing to muscular weakness. The latter can of course be left to gymnasium directors, but where an alteration in the bone or ligaments has already taken place and true scoliosis has been developed, the condition requires the attention of experts. Methods of treatment which are at present in vogue consist of, first, gymnastics thoroughly carried out. A useful adaptation of this has been brought, within a few years, to the attention of the profession in a thorough manner by Dr. Teschner of New York. Second, the method of ligamentous stretching. Where the ligamentous and muscular contractures are too great to be overcome by any gymnastic method and demand stretching, this method is necessary. This has been brought to a valuable degree of usefulness by several Continental surgeons, notably Schulthess of Zurich. The third treatment is that of forcible correction, brought prominently before the profession by several German surgeons, and lately by Wullstein. Quite recently Dr. Hoke of Atlanta has employed operative measures with osteotomy of the distorted ribs which promises to extend the possibilities of successful treatment to cases hitherto regarded as beyond benefit. It is in following in these lines and in improvement of these methods that this distressing deformity can be made curable.

Dr. Lovett's investigations will be much appreciated by his orthopedic colleagues in this community.

Dr. C. F. Painter: I am particularly interested in this apparatus of Dr. Lovett's, as we have been attempting some forcible corrections at the Carney Clinic, following the methods suggested by Wullstein. The apparatus in use there is like his in principle, differing only in the amount of force which can be used. Our cases have not been put up with the helmet attachment to the jacket, which, of course, lays our failure to secure the results which Wullstein claims open to criticism. Though we have succeeded in obtaining considerable correction in some of our cases, it has not been more than could be secured by a good deal less rigorous methods, and has not been maintained. I think the theory upon which Wullstein worked is erroneous, and that he could not reasonably expect to correct a deformity which is fixed, so far as the hardening of the bones is concerned, at the time the cases of bad scoliosis came for treatment, by the same method which he has found would produce these bony changes in a growing puppy.

There are two serious obstacles to the forcible correction of scoliosis; one is that a certain number of cases behave very badly under the fixation of the chest with plaster jackets; in the second place it is not reasonable to suppose that anything can be accomplished by simply lessening the lateral deviation of the column unless the muscles can be strengthened to hold any possible correction secured. It seems unreasonable to secure this muscular strengthening of the short muscles on the concavity of the curve or the stretched muscles on the convexity, unless opportunity is offered for their functional use immediately.

For these reasons forcible correction seems to me reasonable only when used intermittently with jackets and combined with gymnastic work from the start. I should, therefore, regard any method of correction in jackets as simply another resource which we have at our disposal for the limbering up of scoliotics. I believe that this is better accomplished by hyperextension of the spine and application of the jacket in that position than by applying the retention apparatus in a

flexed position. All methods which tend to help in the solution of some of the complicated problems of lateral curvature should be welcomed, for the more devices one is master of, the greater success must attend the treatment of these most distressing deformities.

NEW YORK NEUROLOGICAL SOCIETY.

STATED MEETING Jan. 5, 1904.

PEARCE BAILEY, M.D., President.

PTOSIS RELIEVED BY OPERATION.

DR. B. SACHS presented a young man who had been under his observation for a number of years. He had been apparently well until about ten years ago, when he had an apoplectiform seizure, which resulted in double ptosis and palsy of all of the ocular muscles. There was some recovery, but at the present time there was almost complete paralysis of both recti externi, and the up and down motions were still considerably restricted. The rectus externus of the left side had recovered most. The lesion was evidently in the vicinity of the aqueduct of Sylvius, involving not only the third nerve but the sixth and fourth nerves. For many years this man had had a very persistent tachycardia, and it was assumed that he had had a chronic endocarditis, and that an embolus had passed into the basilar artery. Quite recently another possibility had arisen, *i.e.*, Dr. A. Wiener had found what he considered to be a specific lesion of the fundus. Possibly, therefore, the original condition was a thrombosis resulting in considerable softening. The speaker thought that after a certain length of time, when the ordinary therapeutic procedures had failed to bring about a favorable result, it was proper to resort to surgical means for relieving the ptosis.

DR. ALFRED WIENER, supplementing Dr. Sachs' report, said that before the operation, which he had done, the left eyelid hung down to the full extent. The operation done was that known as the Hess operation. An incision was made along the brow, the skin was dissected away and three deep sutures were inserted so as to practically attach the lid to the frontalis muscle. There had been no sacrifice of tissue, and the natural folds of the lid had been preserved. There were a number of pigment spots on the periphery of the retina, a condition often found in young children suffering from hereditary syphilis. It was extremely probable, therefore, that this man was suffering from hereditary syphilis.

DR. W. M. LESZYNSKY said that if the man had a ptosis and a paralysis of the third nerve, and the operation were done, and there was diplopia, the resulting condition would be worse than before the operation.

DR. SACHS said that he had intended to emphasize the point that if there were a diplopia, other ocular muscles should be cut hereafter and a proper equilibrium of the muscles restored. He had had this done in a number of stubborn syphilitic cases, at the suggestion of an ophthalmologist, and the results had been very satisfactory. He would, therefore, recommend the operation not only in ptosis, but in any ocular palsy of long standing.

POST-DIPHTHERITIC HEMIPLEGIA, PROBABLY OF NEURAL ORIGIN.

DR. JOSEPH COLLINS presented a boy of nine years with paralysis and contracture of the left hand and foot. He had first seen the patient at the request of a surgeon, who suspected a tumor of the cortical motor area. The history was that, two and a half years ago, the child had a severe attack of diphtheria, for which antitoxin was administered on the fourth day. A week later the child was very weak, and his hands, feet and face were swollen. About three weeks after the onset of the disease he began to walk, and then it was noticed that the left foot dragged. A day or two later the left hand was observed to be weak. A week or so after that the left angle of the mouth was seen to be drawn up. Oftentimes on attempting to swallow fluids, they regurgitated through the nose. The mother did not recall the boy's having had choking spells on swallowing. Between two and three months after the onset of the paralysis the hand and forearm began to flex and the hand to abduct, so that the elbow stood out from the body further than the shoulder. The hand became tightly clutched and gradually drew up until it was held behind the head. This condition lasted about a year. During this time the endeavor was made to overcome this position of the hand by making him carry a weight in it and by using a Whitely exerciser. About eighteen months after the onset of the paralysis the face became straight, but the condition of the foot remained such that when he attempted to put on a shoe he had to wait until the toes became extended, and if the shoe were not slipped immediately at that moment he might have to wait half an hour before the flexor contraction or spasm would again relax. He never complained of pain. He attended school during this time, and was always bright in his studies. On admission to the Hospital for Ruptured and Crippled on Oct. 23, 1902, he walked with a limp on the left side, the foot being held in position of marked equinus and slight varus; the left hand was held rigid, with the fingers extended, and the posterior muscles of the leg were in rigid contraction. The toes were flexed. The equinus could be overcome by force. There was slight atrophy of the muscles of the leg, but no paralysis. The left hand was in overextension, but there was no barrier to flexion. On Oct. 28, the astragalo-scaphoid articulation was exposed, and a wedge of bone and cartilage was taken from the adjacent surfaces. The flexor longus hallucis was exposed and cut, the proximal end was drawn down and passed through the scaphoid and sutured to itself and adjacent periosteum. The anterior tibial was cut and shortened, and a tenotomy of the tendon Achilles was made. The foot was put up in valgus position in plaster of Paris. On Nov. 15, 1902, the hand was put up in plaster in a flexed position. On Dec. 13, 1902, when the plaster was removed from the hand, there was marked flexion with slight flexion of the fingers. On Jan. 21, 1903, it was noted that the hand was in extreme flexion. At present, the boy was apparently healthy and well except for the deformity of his left extremities. His ability to walk, run and jump was limited only by the flexed position of the foot. He stood on either foot equally well. There was no paralysis of the muscles of the hip. The fingers, hand, forearm and arm were in a state of flexion, and the fingers and hand inclined to extreme flexion. This contracture could be overcome by the examiner. The knee jerks were present on both sides and equal. There was no tenderness on pressure over the nerves, nor were there any sensory disturbances. There was no atrophy. There was partial reaction of degeneration in the muscles and nerves of the extensors of the forearm and foot and of the peroneal muscles. There was none of the stigmata of hysteria unless the contracture might be considered such. The case was diagnosticated as one of post-diphtheritic neuritis resulting in contracture and faulty attitude simulating hemiplegia. That there might be an hysterical element in it the speaker did not deny.

DR. JOSEPH FRAENKEL called attention to the curious and irregular behavior of the symptoms, and

the absence of organic phenomena. The change in electrical reaction might be explained by the clonic state of the muscles. He was inclined to believe that this was a functional disorder.

Dr. Leszynsky said he had carefully examined this boy previously. According to the history that he had obtained, this peculiar attitude took place very rapidly. He had been impressed with the fact that, on entering the hospital, there was complete extension of the wrist and hand, and that after the hand had been placed in forcible flexion it had remained in that attitude, whereas formerly it had been in extension. He could find no evidence of involvement of the motor tract. He was inclined to look upon the case as of functional origin. According to the history, the extension took place quite early.

Dr. Sachs said that from a very large experience that he had had with infantile cerebral palsy he would not hesitate at all to say that this was a case of that kind. He pointed out that infantile cerebral palsy did occur after diphtheria. The boy had a hemiplegia which was entirely typical, and there were contractures just as in other cases of hemiplegia. There were athetoid movements of a most pronounced character. If, with the eyes closed, the boy was asked to grasp one's hand firmly with the well hand, the affected hand would at once go into the athetoid position. He could not recall having ever seen this condition in hysteria or neuritis. The leg had recovered very much more than the arm. He would not deny the possibility also of a neuritis, but the infantile palsy was a primary condition. He could not believe that any neuritis would give rise to the condition found in the leg. He would like to know if any one present had ever seen athetoid movements with peripheral neuritis. There was probably a post-diphtheritic encephalitis as the original cause.

Dr. C. L. Dana said he was very glad indeed to hear this positive opinion expressed because he had arrived at the same conclusion from a rather hasty examination of the child. To him a condition very characteristic of the cerebral hemiplegia was present in the face.

Dr. Pearce Bailey said that the history of the case did not point very distinctly to a post-diphtheritic paresis, and such a distinctly hemiplegic character would be unusual for a neuritis. The weight of evidence seemed to point to a post-diphtheritic cerebral hemiplegia.

Dr. Collins said he did not know of any hemiplegia of organic origin that entirely spared the upper part of one extremity. There was some involvement of the face and an inability to wink with the left eye, but a large number of people were unable to wink with one or the other eye who had never had hemiplegia. The fact that one hand underwent extension while the other clutched did not seem to him to have any significance, because he had frequently tried this in persons who had no hemiplegia.

TWO CASES OF CONGENITAL CYST OF THE FOURTH VENTRICLE ASSOCIATED WITH BRAIN TUMOR.

Dr. J. Ramsay Hunt reported these cases, presenting photographs and specimens. He said that both cases were examples of brain tumor in young subjects, occupying the left optic thalamus and the right crus cerebri respectively. In addition, the fourth ventricle in both cases contained a large cyst, primarily attached to its floor, penetrating into the substance of the pons, coursing through its structures and terminating in immediate structural relation with the tumor. The clinical course of the disease in both cases was typical of brain tumor, and permitted the correct localization of the growth. Antedating the symptoms of brain tumor no certain history of central symptoms or mental defect was obtainable. In the second case the patient was said to have been subject to headaches with attacks of vertigo and nausea. The first patient was a boy of seven, who developed general symptoms of brain tumor with right hemiparesis and right hemiataxia. There was paralysis of the right side of the face with paresis of the left external rectus and with nystagmus. Hearing was impaired on the right. The second patient was a boy of seventeen who, six weeks after a fall on the occiput, developed the general and focal symptoms of brain tumor in the right crus cerebri. Weber's syndrome was present. On exposing the fourth ventricle, at the autopsy, a large cyst was found there in both cases, firmly attached to the floor of this ventricle. By serial sections he had demonstrated that in both cases the cyst dipped down in the pons, coursed forward and was in immediate structural relation with the tumor in both cases. There was nothing in the walls of these cysts to suggest a parasitic origin, while there was much to point to a congenital origin. The frequency of glioma in this locality was well known. The coexistence of a tumor formation still further supported the view already expressed. These cases were unique in his pathological experience, and he had been unable to find their counterpart in the literature.

A CASE OF PRIMARY SCLEROSIS OF THE POSTERIOR COLUMNS FOLLOWED BY A DISSEMINATED SOFTENING OF THE OTHER WHITE COLUMNS.

Dr. Joseph Collins presented this report. The clinical picture, he said, was so typical that the diagnosis was made during life. The patient was a housepainter, forty-two years of age, whose only previous illness had been severe attacks of colic. There was no history of syphilis, gonorrhea or the excessive use of alcohol. In 1900 he began to complain of trembling and stiffness of the hands, associated with intense paresthesia. Later on, there was pain in the back. During the following year his principal complaints were manual paresthesia and general weakness. There was no desire for sexual intercourse. All this time he was under treatment for chronic lead poisoning. In January, 1902, he rapidly became paraplegic, and since then had been bedridden. He was admitted to the City Hospital in March, 1902, and when first examined by Dr. Collins, on April 11, the man appeared to be suffering from Bright's disease. He could move the lower extremities slowly; there were knee jerks present on both sides. The Babinsky reflex could also be elicited on both sides. Tactile sensibility was impaired over the lower extremities. Thermal sensibility was preserved, but was slow below the knee. Pain sensibility was preserved. Deep sensibility was lost. There was prompt response to the faradic current. The pupils were equal and responsive. Bed sores were developing over the sacrum. The blood examination showed a predominence of small mononuclear cells and there was only 65% of hemoglobin. On April 27, it was noted that there was complete flaccid paraplegia; the left lower extremity was edematous; there was incontinence of urine and feces. He refused to take food up to the time of his death. The autopsy was made twenty-four hours after death. The brain and spinal cord were prepared in the usual way, and showed two distinct sets of lesions, sclerosis and softening. The areas of softening appeared to be very recent. In general, they involved the columns of Burdock, the posterolateral portions of the crossed pyramidal tract

and the cerebellar tract. The oblongata, pons and motor cortex were normal. The sclerosis appeared to be a primary one following pretty closely the system of fibers in Goll's tract. No thrombi or pathological changes of the blood vessels were found, and the blood examination showed this fluid to be fairly normal. The genesis of the softening was still obscure.

DR. C. L. DANA said that this description followed closely those of cases of combined degeneration of the spinal cord with terminal softening. He did not quite understand whether the reporter put his case in this group, yet, to his mind, the case corresponded very closely with typical cases of that kind, a considerable number of which it had been his fortune to observe. Sometimes these cases were associated with a pernicious anemia; sometimes there was a severe primary anemia, while at other times there was no anemia at all. It was unfortunate that neurologists had not as yet agreed upon a name for this affection. The most common name was combined degeneration of the spinal cord associated with toxic states. The pathological conditions reported in this paper were very similar to those already reported. It was only in the minority of cases that there were areas of terminal softening. He was not prepared to admit that there were two distinct processes going on in the spinal cord. The disease began slowly, affecting by preference spots in the posterior columns, and subsequently the lateral columns. If the patient's condition were bad at this time, an acute process developed, but probably essentially of the same nature. The etiology of the toxic condition was as yet unfortunately involved in obscurity.

DR. COLLINS said that his case was reported as one of primary sclerosis of the columns of Goll with secondary softening in the other white columns, the paper being entitled, "A Study of Subacute Sclerosis of the Spinal Cord of Toxic Origin." His case differed materially from those reported by Drs. Dana and Putnam in that the sclerosis was sharply and completely limited to the columns of Goll. In the other cases the sclerosis predominated in the posterior columns and in the crossed pyramidal tract, and this accorded in the main with the clinical history. The fact that his patient had suffered severely from lead poisoning and had subsequently developed a cachexia seemed to throw a little light on the etiology.

LYMPHOCYTOSIS OF THE CEREBROSPINAL FLUID.

DR. JOSEPH FRAENKEL read a paper on this topic. He said that he had endeavored to study this subject in 47 cases, but in 14 of these the tappings had failed to give any cerebrospinal fluid. There were seven cases of tabes, all of long duration, and all of these cases showed marked increase of lymphocytosis. Six out of the seven cases of multiple sclerosis showed lymphocytosis. The tapping was done upon the patient in the sitting posture, preferably between the third and fourth lumbar vertebræ, or at the level of the iliac crests. From 5 to 8 cc. of the fluid were collected for each examination, and then dentrifuged. The tappings were made under chloride of ethyl spray. In some of the cases headache and nausea followed lumbar puncture, but they were usually overcome by saline injections.

DR. SACHS said that in the two cases in which lumbar puncture had been tried by him in order to distinguish between pseudotabes and tabes the examination proved entirely negative and of no diagnostic value. Hitherto the reports on this subject had been discouraging because of their contradictions. Lumbar puncture should never be attempted whenever there was a possibility of the existence of a cerebellar neoplasm, as several instances of sudden death following this procedure in such cases had been reported.

DR. DANA said he had made lumbar puncture now in 26 cases, 21 of which were successful. About 12 of these cases were cases of paresis in which it was desired to receive some diagnostic aid. In two the fluid was clear; in others there was a lymphocytosis. He had found the procedure helpful in diagnosticating certain acute cases coming into the insane pavilion. The procedure was easy after a little practice, and could be done almost painlessly by using 30 minims of ½% solution of cocaine injected ten minutes before the tapping. The procedure had proved helpful in one or two cases of spinal trouble. He believed it was not only of value in diagnosis but that it would prove useful in time in therapeutics. Lumbar puncture almost always caused headache or vertigo for a day or two, sometimes for a week, and often it was very distressing. He believed this could be avoided by removing only 4 cc. of the fluid, a quantity sufficient for diagnostic purposes.

DELIRIUM GRAVE; A CRITICAL STUDY, WITH REPORT OF A CASE WITH AUTOPSY.

DR. W. B. PRITCHARD presented this paper. He said that all authors agreed that the disease was very uncommon and most writers agreed that it was chiefly found among women. The immediate exciting causes were apparently numerous and various. Typhus and typhoid fever, or other prolonged infections, might be followed by delirium grave. The clinical picture was quite distinct and constant. Following a sudden or prolonged strain, the patient developed a maniacal condition with violence and incoherence. Hallucinations and delusions appeared, usually related to the visual sense, and the temperature was usually raised from one to five degrees above the normal. Again and again transient remissions might occur, but they became less and less complete and less frequent. Emaciation was sometimes rapid, followed by exhaustion, coma and death in a short time. At least two fundamentally different diseased conditions had been confused — one obviously organic, inflammatory and due to toxins or trauma; the other giving chiefly negative pathological findings. He would suggest the use of the term "delirium grave" for this group, and the application of the terms "pseudo-delirium grave" or "acute febrile delirium" to the first group. Many cases of meningitis and of toxic encephalitis had been reported as delirium grave. In ordinary acute mania there was not the same tendency to rapid and fatal collapse, and the hallucinations and delusions were more systematized. The disease was of extremely grave prognosis, nearly all cases terminating fatally. Death usually occurred from exhaustion; those who escaped death passed into a condition of dementia. The case reported occurred in a woman of forty-three, who had been subject to many and severe nervous strains. On Dec. 12 she suddenly developed the most violent mania. The delirium and mania were only temporarily controlled by drugs, and she died on the sixteenth day. A noticeable peculiarity was an almost continuous expectoration. Incontinence of urine and feces developed a few days before death. The autopsy was made four hours after death by Drs. McPhee and Larkin. Sections were made from all the regions of the brain. No changes in the blood vessels were noted; the chief changes were eccentricity of the nuclei with ragged cell outlines and loss of chromatic bodies. In the cerebellum, Perkins' cells were mere

shadows. These lesions had been found in a great many other conditions.

Dr. Adolf Meyer was of the opinion that acute delirium grave had, among alienists, much the same position that Landry's paralysis had among certain affections of the spinal cord. The delirium under discussion was uniform and unmistakable in that it could not be analyzed owing to the excited condition of the patient. He had not yet met with a single case in which there had been reason to doubt the diagnosis of delirium grave. In some of these meningitis had only been discovered by microscopical examination; in others, pneumonia or some other condition had spoiled the purity of the clinical picture. He thought the majority of alienists took a somewhat different position from Dr. Spitzka on this subject, believing it to be a peracute phase, but not a clinical entity.

Dr. Pritchard said that the object of his paper was to endeavor, if possible, to clear up the subject by separating the cases of meningitis, pneumonia and the like from true delirium grave, and emphasizing this differentiation by reporting a striking case coming under his own observation. He was of the opinion that the vast majority of alienists of to-day did recognize delirium grave as a clinical entity, although of obscure etiology.

Recent Literature.

The Medical Annals of Maryland. 1799–1899. Prepared for the centennial of the Medical and Chirurgical Faculty. By Eugene Fauntleroy Cordell, M.D. Illustrated. Baltimore. 1903.

This volume of nearly 900 pages is the result of a plan adopted by the Medical and Chirurgical Faculty of Maryland in 1898 for the proper celebration and commemoration of the centennial of the faculty. The work is arranged in three divisions, — an historical section, a biographical section and a chronological section. The first, as its name implies, deals with the work of the society during the century of its existence; the second gives the names and a brief record, when obtainable, of about 2,400 persons who have been members of the society. In spite of every effort small information was obtainable of many of the 101 charter members, a matter, naturally, of regret. The third part, making use largely of the historical researches of the late Dr. John R. Quinan, is concerned with matters of chronological interest. The editor of the volume has been assisted in his work by the following committee: Drs. William Osler, Thomas A. Ashby, Harry Friedenwald, Henry M. Hurd and George J. Preston.

The volume is a worthy commemoration of the event it is designed to celebrate, and contains a large amount of information which should prove of vital interest to the student of the medical history of Maryland which is epitomized in the hundred years which the book covers. It is admirably printed and bears evidence of the assiduity of the editor and his collaborators. A number of half-tone reproductions of distinguished men and other illustrations of general interest embellish the volume.

High Frequency Currents in the Treatment of Some Diseases. By Chisholm Williams, F.R.C.S. (Edin.) 8vo. pp. xvi, 222. With 75 illustrations. London: Rebman, Limited. 1903.

The use of electrical currents of high frequency and high potential is increasing and the value of such currents in therapeutics seems to be acknowledged, especially in the treatment of tuberculosis and certain skin diseases. The volume before us gives a somewhat full account of the various forms of apparatus required, and the methods of using them, with the results of treatment in various cases. The author unfortunately presupposes a considerable knowledge of electricity on the part of the reader, so that the book is hardly adapted for one beginning the study of high-frequency currents.

Organic Nervous Diseases. By M. Allen Starr, M.D., Ph.D., LL.D. 8vo. pp. viii, 751. Illustrated with 275 engravings in the text and 26 plates in colors and monochrome. New York and Philadelphia: Lea Brothers & Co. 1903.

"It is now possible," says the author in his preface, "to trace any symptom presented by a patient to some disturbance of function in a definite nerve center or nerve tract." While this is certainly the goal of our diagnostic efforts, our knowledge is still far too inadequate to attain unto it, and the present volume by no means extends our knowledge far enough to warrant the claims of the preface. The very title of the book is a reversal toward doctrines that are obsolescent, since one aim of modern neurology is to remove the taint of ignorance implied by the word functional and establish a definite pathology of the "functional" disorders. The book itself is a treatise upon nervous diseases, laying somewhat particular emphasis upon localization and upon surgical treatment, and omitting any consideration of that large class of nervous diseases which were once called "functional," except the various forms of neuralgia. Within these limitations the work is of uneven merit. The author's skill in a clear and simple presentation of the essential facts of a subject is well known, and that is, of course, manifested in the present volume, his presentation being enriched with the results of his own large clinical experience and by many excellent diagrams and illustrations. Some of the chapters are clear, accurate and an excellent presentation of the latest doctrines upon the subjects of which they treat. Others are thoroughly banal, defective and far behind our present knowledge. They read as if they had been written five or six years ago and published without revision. In addition, there are many statements which are either inaccurate or far too positive, and show a lack of care and a failure to note recent investigations. In spite of these grave faults the work contains much of great value and it will in many ways prove helpful to the neurologist, although it is of too uneven merit and too incomplete to place in the hands of the student.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MARCH 17, 1904.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.50 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

DUSTY STREETS.

THE complaint periodically heard in this community of the unhygienic condition of streets finds its echo in London, and we have no doubt, if investigation were carried further, it would be found that all cities exposed to wind and dirty streets would be found in a similar plight. At a recent meeting of the Sanitary Institute of Great Britain, alluded to in the *Lancet*, the evening was devoted to a discussion of the relation of streets and thoroughfares to public health in the hope that vast municipal schemes might temporarily be subordinated to the humble duty of effective scavenging.

Apparently the most important paper read at this meeting was by Dr. L. C. Parkes, medical officer of health of Chelsea, who discourses upon the compound known either as London mud or London dust according to its condition of moisture. He dwelt upon the perfectly familiar facts that such material in pulverized form is of necessity a source of irritation to the bronchial mucous membranes, and that, difficult as it may be to trace special diseases to this flying dust as a source, nevertheless, the fact cannot be doubted that such material must be capable of doing positive harm. Apart from the actual production of disease, the general discomfort and damage to property should receive consideration. Dr. Parkes, for example, notes the fact that attempts to exclude dust from cases containing the more valuable books in the Library of the British Museum have met with only partial success. Microscopic examination shows this dust to be derived directly from the streets. Street dogs he regards as an "unmitigated" nuisance, and urges that restrictions be laid upon their use of highways and foot paths. He disapproves of macadamized streets, and urges that they be superseded as soon as may be by wood or asphalt which might be effectively cleansed by daily washing.

All this sounds familiar, and is certainly, as experience has shown, as applicable to us as to London. Boston has the reputation at least of being a peculiarly windy city; its experimental pavements are of great variety; its dust under proper weather conditions is always apparent. We recall a meeting held several years ago by the Boston Society for Medical Improvement analogous to the one we have just alluded to in England. The dangers and discomforts and various means of bettering the conditions were discussed at length by specially qualified speakers. The dust of the streets was magnified by a lantern projection on the screen, and everything legitimate was done to impress upon municipal authorities the importance of the entire matter. The results, however, have not been conspicuous. We still have dirty streets and the inevitable accompaniment of dust and dirt.

The continuous covering of snow during the past winter has definitely relieved the usual conditions, and no doubt has conduced to a greater degree of health in the community than would otherwise have been the case. The problem in general is clearly one for the municipal authorities to solve. In the meantime physicians should persevere in their investigation of the actual danger which lurks in the familiar dust storm. If we could prove definitely that disease of any sort is regularly induced by these conditions, municipal action could possibly be hastened. The present situation appears to be here, as in London, much discomfort and the possibility of disease.

REPORT OF PUBLIC HEALTH AND MARINE HOSPITAL SERVICE.

THE annual report of the Surgeon-General of the Public Health and Marine Hospital Service of the United States for the year 1902 is before us. We have previously noted the reforms and consequent increased efficiency of this branch of the public service. Surgeon-General Wyman finds much cause for the belief that the possibilities of increased usefulness under the act of July 1, 1902, will be manifest in the immediate future.

The foundation provided by Congress during the past year makes possible the development of the service in a measure hitherto impossible. He also feels that now an influence for the public welfare is offered far beyond any opportunity of a like character that has been presented in the history of the country.

At the end of the fiscal year under consideration the commissioned corps of the service numbered 105 commissioned officers, including the surgeon-general, 29 surgeons, 27 passed assistant surgeons and 48 assistant surgeons. Officers presenting themselves for examination for promotion were uniformly successful. New hospitals are being established at New York, Buffalo, Pittsburg and Savannah, and measures have been taken toward selecting sites and erecting suitable buildings.

Regarding the diseases which came under the observation of the Marine Hospital Service, it appears that no case of yellow fever occurred in the United States during the year. In San Francisco 39 cases of plague were reported with but one death. Smallpox had occurred in 44 states and territories to the number of upwards of 50,000, with nearly 2,000 deaths, the mortality being 3.31%. A commission appointed to investigate the origin and prevalence of leprosy in the United States reported as follows: That there were present in the United States 278 cases of the disease, probably an incomplete census because of the impossibility of discovering all cases. Of the cases observed 145 were born in the United States, 120 in foreign countries, and the birthplace of the remainder was unknown. Twenty-one states and territories are known to contain lepers. As a result of this investigation, the commission recommends the establishment of at least one national hospital for leprosy, to be maintained under the supervision of the general government. Under present conditions of improved hygiene and knowledge of the nature of the disease these figures cannot be regarded as in the least menacing. Isolation is, however, undoubtedly a wise precaution. On the scientific side, the various researches have been undertaken on the general question of the etiology of yellow fever and on various matters of hygienic importance.

The greater part of the report, as usual, is taken up with contributions of a clinical or laboratory character from the various division officers located in different parts of the world. Numerous illustrations of interest, illustrative of quarantine or sanatorium construction, are inserted in the text; in general, we find the report stimulating and indicative of the increasingly thorough work of scientific value which is being carried on by the Marine Hospital Service.

INTERSCHOLASTIC SPORTS.

The Indoor Interscholastic Athletic Meeting, under the auspices of the Boston Athletic Association, took place on Saturday, March 19, at the Mechanics Building on Huntington Avenue. It served to emphasize the statements made in these columns a few weeks ago (Feb. 11) in relation to schoolboy athletics.

Before the contests a meeting of the officers of the association was held, at which many of the contestants were present. This meeting was addressed by the managers of the Harvard and Yale Track Teams, and also by Mr. Clark of the Boston School Committee. The last speaker dwelt on the possible dangers of Interscholastic Athletics as viewed from the standpoint of a practical athlete. In the main his views coincided with those already expressed in these columns.

It seems to be a fact that the large majority of schools sending teams to these contests do not have any routine medical examination, and that the boys are subject to the direct and absolute authority of a professional or semi-professional trainer. The boys are allowed to compete in several events, and at times are encouraged to do so. The amount and severity of the training depends entirely upon the judgment of the professional coach. The frequent disappointment in the performance of individuals, of whom much had been expected in certain events, expressed at times in no uncertain terms, is only too often due to overtraining which is entirely the fault of the coach. And the reputation of the coach is usually a matter of more concern than the welfare of the boys.

Another thought suggested by this school meeting is the advisability of giving up the mile run at the indoor meeting. The dust, the poor ventilation, the hard and crowded track and the sharp corners are all arguments against the indoor mile. The outdoor mile is sufficiently severe for schoolboys and it should be limited to the strongest and most mature students; but, at least, it is run in the open air and on a wide four-lap cinder track.

It is certainly time to supervise school athletics more closely. The possibilities of injury are many, and the manifestations of overwork

or overexertion may not be apparent for months or even years. If present conditions continue, they will inevitably bring discredit upon the interscholastic games.

MEDICAL NOTES.

A CANTATA DEDICATED TO DR. WELCH. —At a concert of the Washington Sængerbund, held March 20, a cantata, "Hymne an Hygiea," composed and orchestrated by Dr. John C. Hemmeter of Baltimore and dedicated to Dr. William H. Welch, was given.

POSTPONEMENT OF HENRY PHIPPS INSTITUTE LECTURE. — It is announced that a cable from Professor Maragliano states that through illness he will be unable to give his lecture under the auspices of the Phipps Institute scheduled for March 28. It has, therefore, been indefinitely postponed. The Henry Phipps Institute will entertain at dinner on Monday, the 28th inst., the delegates who have been called to meet in Philadelphia to consider the question of a National League against Tuberculosis, and the holding of an American Congress against Tuberculosis. Dr. F. L. Flick will give a luncheon to the delegates on the same day just before the meeting, which has been called for 3.30 o'clock. At this meeting an abstract from Professor Maragliano's paper will be read.

LEPROSY IN NEW SOUTH WALES. — In a report of the Board of Health of New South Wales for the year 1901, rendered the end of December, 1903, there appears the following summary in regard to leprosy: The total number of persons admitted since 1883, when patients first began to be received (though the notification of leprosy was first made compulsory and the detention of lepers provided for by law only towards the end of 1890), is 78. Distributed under nationalities, the account stands as follows: Natives of New South Wales, 21, of whom 15 have died and 1 was released; of Queensland, 1, deceased; of England, 4, of whom 2 have died; of Ireland, 2, deceased; of New Zealand, 1, deceased; of Fiji, 1, deceased; of Germany, 2, of whom 1 has died; of Belgium, 1, deceased; of the United States of America, 1; and all of these were whites, of European descent. There were also 37 natives of China, of whom 12 have died and 21 have been returned to their own country; of India, 2, deceased; of the West Indies, 1, discharged in 1885; of Java, 1; of Tanna (New Hebrides), 1, deceased; of New Caledonia, 1, deceased; of South Sea Islands, 1; and all of these were colored people.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon March 16, 1904, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 47, scarlatina 21, typhoid fever 5, measles 157, smallpox 0.

DEATH FROM ANTHRAX. — It is reported that a morocco workman in Lynn has recently died from anthrax, presumably contracted from the handling of South American goat skins.

BOSTON MORTALITY REPORT. — The number of deaths reported to the Board of Health for the week ending March 19 was 253, as against 225 the corresponding week last year, showing an increase of 28 deaths and making the death-rate for the week 21.87. The number of cases and deaths from infectious diseases was as follows: Diphtheria, 47 cases, 7 deaths; scarlatina, 25 cases, no deaths; typhoid fever, 6 cases, 3 deaths; measles, 191 cases, 9 deaths; tuberculosis, 44 cases, 30 deaths; smallpox, no cases, no deaths. The deaths from pneumonia were 48, whooping-cough 1, heart disease 18, bronchitis 5, marasmus 2. There were 4 deaths from violent causes. The number of children who died under one year was 47, under five years 67, persons more than sixty years 52, deaths in public institutions 82.

BEQUESTS TO HOSPITALS. — By the will of the late William Litchfield of Lexington, Mass., the following institutions in and about Boston, among many others, are beneficiaries: Kindergarten for the Blind, Jamaica Plain, $5,000; Boston Lying-in Hospital, $3,000; Home for Aged Men, $5,000; Children's Hospital, $5,000; Cullis Consumptives' Home, $5,000; New England Hospital for Women and Children, $3,000; Washingtonian Home, $5,000; Home for Aged Couples, $5,000; Massachusetts General Hospital, $5,000, income for free beds; Massachusetts Homeopathic Hospital, $5,000, income also for free beds. The Perkins Institute and Massachusetts School for the Blind receives property in Charlestown. The Kindergarten for the Blind, Jamaica Plain, is also made residuary legatee of certain property in West Somerville

NEW YORK.

BEQUESTS TO HOSPITALS. — Among the charitable bequests of the late Elizabeth Y. Wright of Glen Cove, Long Island, N. Y., is $5,000 to the Nassau Hospital at Mineola, Long Island.

ELSBERG CORONERS' BILL. — On March 7, by a vote of 28 to 13, the State Senate passed the

Elsberg Coroners' Bill. The measure abolishes the office of coroner in the city of New York at the expiration of the terms of the present coroners and authorizes the establishment by the Board of Health of a Bureau of Medical Examiners, with a chief examiner and assistants.

Bequest to Seney Hospital. — By the will of the late Smith Lafayette Russell $5,000 is left, as a trust fund, to the Seney Methodist Episcopal Hospital in Brooklyn.

Pneumonia in Rochester. — The Health Department of Rochester, N. Y., has ordered that physicians shall report all cases of pneumonia occurring in their practice, thus placing it in the class of infectious diseases. A map of the city is to be kept at the office of the department, on which the location of the cases will be designated, and notes will be made of the sanitary conditions accompanying them.

New Buildings of Mount Sinai Hospital. — The fine new buildings of the Mount Sinai Hospital, occupying the block extending from Fifth to Madison Avenue and from 100th to 101st Street, were thrown open to inspection on March 15. They are ten in number, all of them, with the exception of an isolation house, connected by corridors on the ground floor. The institution is very completely equipped in all its departments, and will comfortably accommodate 450 patients in the wards, in addition to 52 in the private pavilion. On the Fifth Avenue side it faces the upper part of Central Park.

"Privileged Medical Testimony." — On March 15 the Court of Appeals, at Albany, handed down a decision (in which only a bare majority of the court concurred) in favor of the plaintiff in an action by Henrietta Meyer of New York against the Supreme Lodge, Knights of Pythias. This decision involves the question of "privileged testimony," and the point at issue was whether the testimony of a physician who declared that the plaintiff's husband, Emanuel Meyer, committed suicide, should be excluded. According to the terms of the benefit certificate held by Meyer, a recovery for death was not allowed in case of suicide. The Court of Appeals agrees with the lower courts in deciding that the physician's testimony could not be accepted as evidence, and this allows the plaintiff to recover. On the trial she succeeded in having such testimony excluded. The defendant raised the point that the section under which the trial court made its decision was not applicable in the case, inasmuch as the Knights of Pythias is not a New York corporation, but a Federal corporation. The courts, however, decided that the laws of the state were applicable to the contract between it and Meyer, notwithstanding the fact that the defendant's headquarters were in Illinois.

Vital Statistics for 1903. — The official vital statistics of the city for the year 1903 have just been issued by the Health Department. The total number of deaths was 67,864, and of reported births, 94,755. The number of deaths in infants under one year was 14,402, and in children under five years, 22,044. The annual death-rate in the city was 18.18. The lowest rate was in the Borough of Queens, 14.65, and in the other boroughs it was as follows: Richmond (Staten Island), 16.93; Brooklyn, 17.18; the Bronx, 17.75; Manhattan, 19.30. The diseases causing the largest number of deaths were the following: Pneumonia (6,402) and bronchopneumonia (3,312), 9,714; pulmonary tuberculosis, 8,019; Bright's disease and nephritis, 5,636; organic diseases of the heart, 4,771; diarrhea and enteritis (under two years of age), 4,439; congenital debility and malformations, 3,657; cancer and other malignant tumors, 2,609; congestion, hemorrhage and softening of the brain, 2,573; diphtheria and croup, 2,190. From other infectious diseases the mortality was as follows: Scarlet fever, 734; typhoid fever, 653; measles, 508; influenza, 418; whooping-cough, 324; smallpox, 5. The following is the number of cases of tuberculosis and of contagious diseases reported: Tuberculosis, 15,214; diphtheria and croup, 18,317; measles, 13,689; scarlet fever, 10,887; typhoid fever, 3,671; smallpox, 43. In addition, the following cases of contagious disease were reported from quarantine: Measles, 334; scarlet fever, 52; smallpox, 24; diphtheria and croup, 10.

Decision regarding Appropriation for Hospital Patients. — Justice Hatch, in writing the opinion of the Appellate Court, now says that the city since 1898 has appropriated 60 cents a day for each hospital patient, but the constitution provides that the money shall not be paid unless the hospital complies with the rules of the State Board of Charities. The grant, he holds, does not devote the land to the use of the corporation for its corporate purposes, but in effect gives it to be sold for the purpose of creating a fund operating as an endowment, over which neither the city nor the Board of Charities has control. "Nor does any case, so far as we

have been able to find," the opinion continues, "support such a grant. On the contrary, the expression of the courts on this subject is to the effect that all appropriations must be subject to control of the State Board of Charities, and such is the constitutional provision. To sustain these grants, therefore, would be again to open the door to the evils which arose prior to the constitutional prohibitions upon the Legislature which were passed to remedy such evil. We reach the conclusion, therefore, that these grants are in all respect gifts and endowments, and that as such they are violations of the constitutional provision of the state."

Miscellany.

UNUSUAL COURSES, UNIVERSITY OF CALIFORNIA.

AT the next summer session of the University of California, which will be held in Berkeley for the six weeks beginning June 27 and ending Aug. 6, a number of European scientists will be on its teaching faculty. Prof. Svante A. Arrhenius, the physical chemist of the University of Stockholm, will give in English a course of lectures on the application of physical chemistry to serumtherapy, in which he will make public his most recent and hitherto unpublished conclusions. Professor Arrhenius will give another course upon the general subject of physical chemistry.

Sir William Ramsay of London is to be another member of this summer faculty, and is now preparing a course of lectures to be published later, giving his views upon the recent developments in chemical theory, dealing with the ion and the electron and illustrated experimentally by the behavior and properties of radium.

Prof. Hugo de Vries, the botanist of the University of Amsterdam, will deliver in English a course of lectures on natural plant breeding, giving his views on species and varieties and their origin by means of mutations. The lectures will be illustrated by drawings and by specimens. The following will be the sequence in which he will deal with the subject: Elementary species, constant varieties, ever-sporting varieties, mutation and fluctuation.

Correspondence.

ARRESTED TUBERCULOSIS: SUBSEQUENT HISTORIES OF CASES TREATED AT THE SHARON SANATORIUM.

BOSTON, March 17, 1904.

MR. EDITOR: Will you allow me to reply to Dr. F. T. Lord's criticism [1] of my recent article entitled "Arrested Tuberculosis. Subsequent Histories of Cases Treated at the Sharon Sanatorium from 1891 to 1902?" [2]

[1] Boston Med. & Surg. Journ., Feb. 25, 1904, pp. 224, 225.
[2] Journ. Amer. Med. Assoc., Nov. 14, 1903.

Dr. Lord has shown me the unusual courtesy of referring to me the substance of his recent letter before publishing it, and was kind enough to say that inasmuch as he thoroughly approved of sanatorium treatment and was unwilling to seem to cast a slight upon the cause, he hesitated about publishing his article. I unhesitatingly requested him to say whatever he thought right, inasmuch as the truth is what we all desire in these matters, and frank discussion is the surest way of reaching that end.

In Dr. Lord's desire for scientific accuracy of all terms, he has my most sincere sympathy. No one, I think, can possibly desire that more than myself. But in his recent article, while I am impressed by his remarks, I am very far from being convinced of the correctness of his views.

In any tabulated list of cases such as I have given, I am convinced that it is well-nigh impossible to convey to the reader the clinical picture which any one case or set of cases may have presented to the medical attendant. No one will deny, I am sure, the essential importance of the previous history and the general aspect of a patient, apart from the physical signs found, when tubercular disease is suspected.

In the cases reported as tuberculosis, although not showing bacilli in the sputa and in which the tuberculin test was not given, I have distinct and vivid pictures of them all, and while not wishing to claim infallibility in my own powers of observation, I can unhesitatingly say that they all, in my opinion, showed the distinct symptoms of latent or definite tubercular disease sufficient to make me feel practically certain of the diagnosis. It is a common experience in sanatoria and elsewhere to find patients who continue for weeks, even months, with cough and expectoration which does not contain tubercle bacilli, but which finally shows the presence of the germ. It is perfectly reasonable to suppose, therefore, that in many cases under treatment the prominent symptoms are all checked before the bacillary stage has been reached.

Dr. Lord is evidently an ardent believer in the use of tuberculin as a means of diagnosis, although he frankly admits that the only reliable proof of *pulmonary* tubercular disease is the presence of tubercle bacilli in the sputa. It may be well for me to say here that I cannot put myself in the ranks of those who believe in the free use of tuberculin. To its indiscriminate use and to the sometimes careless methods of claiming reaction when the patient has not been under the strictest supervision, I am strongly opposed. A few years ago, at a meeting of the Medical Improvement Society, I stated that up to that time I had never used tuberculin for diagnostic purposes, although earlier in my practice I had experimented with it therapeutically, only to give it up; and that although I was, perhaps, foolishly conservative, I was not wholly convinced of the wisdom of its use, nor could I conquer then a repugnance to giving it. Since then, yielding somewhat to the opinions of those in whom I had faith, I have occasionally used it in doubtful cases at Sharon and Rutland, where patients could be closely watched, simply as a means, if possible, to convince others of the results in doubtful cases. I regret to state that I have frequently found myself, in consequence of its use, more in doubt than before, and have in a few instances made mistakes in discharging patients who failed to react to the maximum dose, and who in later weeks showed symptoms of disease, cough, blood-spitting, etc. In one case 10 mgm. of tuberculin given carefully failed to cause a reaction in a patient who a few days before had shown bacilli in the sputa. A small number of cases, it may be said, but sufficient to show the possibility of grave error. It should be stated, moreover, that many patients refuse flatly to take the test, a position which adds to the embarrassment and difficulties besetting those who are attempting conscientiously to do their best for the patient, and at the same time to employ what are considered scientific methods.

As to the correctness of Dr. Lord's attitude about all cases which show after repeated examinations no tubercular but numerous grippe bacilli in the sputa, I must confess to being quite unconvinced. Opposed to the fact of Koch's statement that he believes many cases of apical

catarrh to have their origin in grippe and not in tuberculosis, we have Beck's statement that in most cases in which apical catarrh was present with symptoms of grippe, he found the tuberculin reaction to be overwhelmingly positive.[3] So we have conflicting views among men of great experience.

In Dr. Lord's excellent work, "Eleven Acute and Eighteen Chronic Cases of Influenza,"[4] I find that the tuberculin test was given apparently in only three of the chronic cases and none of them came to autopsy. It would be interesting to know the subsequent histories of these cases a few years hence; but from Dr. Lord's papers, I fail to see how they can be proved to be *non-tubercular* simply from the failure to find tubercle bacilli in the sputa while under observation, and I am strengthened in this opinion from the fact that one of our eminent pathologists states that of the chronic pulmonary cases which come to autopsy in his experience, he finds only a small percentage which are non-tubercular in origin.

Lastly, I must state that Dr. Lord's attempt to classify my cases and establish any theories upon a difference in the mortality list of those who had bacilli and those who did not, is absolutely untenable. He forgets, or the tables have not made it evident to him, that the majority of the nine who had bacilli in their sputa and who died were fairly advanced cases in whom an arrest of disease was really unexpected, and one died from another cause during operation, an eminent practitioner of this city, just before her death, having failed to find in her chest evidence of the pre-existing disease. Of the three patients who failed to show bacilli while at Sharon and who died later, one, who had also a mitral lesion, was a typical case of "galloping consumption" after she had left Sharon and had returned to a damp house; the other, with signs in both apices, died of "phthisis" undoubtedly, as stated by her physician; of the third there is no record, but from the previous history there was every evidence of a tubercular tendency, to say the least.

Even in cases of undoubtedly tubercular nature with bacilli in the sputa, we find the course of the disease as different in different subjects as black is from white, an experience which I am sure Dr. Lord must have had also.

His attempt, therefore, to suggest the possibility of a difference in prognosis in the divisions which he makes of my cases on the strength of the presence or absence of bacilli is to me quite untenable.

No one can have greater respect than myself for what bacteriology and laboratory work generally have done for medicine; but I am free to confess that I think we are now apt, too often, to lay stress upon laboratory evidence at the expense of clinical experience, and by so doing are not infrequently led astray. In this opinion I know I am not alone. One thing is certain, in more than twenty years of practice and covering the examination of consumptive cases numbering well up into the thousands, I have never yet had reason to doubt the wisdom of what was dinged into my ears from my earliest medical infancy, viz.: "If you find any change in the respiration or the percussion note in one or the other apex of the lung beyond the normal change which usually exists in the right apex, if you hear a single rale in the same position, especially if accompanied by malaise, loss of flesh, slight fever, with or without cough and expectoration, *watch your patient for he is in danger.*

Whether or not the future shall absolutely prove to us that such cases are often due to some disease other than tuberculosis, I still hold now to the belief that, clinically speaking, the result is likely to be the same to the patient, and it is of vital importance to him at least that we do not split hairs in making a diagnosis.

In conclusion, let me say that I fully appreciate Dr. Lord's excellent work and his laudable desire for scientific accuracy. I can but feel, however, that to follow out his suggestion as contained in his letter would, with our present imperfect knowledge, but add to the unfortunate confusion which to a certain extent must exist in medical nomenclature.

Respectfully yours,

VINCENT Y. BOWDITCH, M.D.

Deaths reported, 4,289; under five years of age, 1,105; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 921, acute lung diseases 1,081, consumption 454, scarlet fever 44, whooping cough 10, cerebrospinal meningitis 16, smallpox 6, erysipelas 16, puerperal fever 27, measles 55, typhoid fever 67, diarrheal diseases 122, diphtheria and croup 78.

From whooping cough, New York 3, Chicago 1, Philadelphia 2, Baltimore 2, Pittsburg 1, Fitchburg 1. From smallpox, Philadelphia 6. From cerebrospinal meningitis, New York 11, Pittsburg 2, New Bedford, North Adams and Gardner 1 each. From erysipelas, New York 5, Chicago 1, Philadelphia 2, Baltimore 1, Pittsburg 1, Boston 4, Taunton 1, North Adams 1. From measles, New York 30, Philadelphia 10, Pittsburg 1, Boston 14.

In the seventy-six great towns of England and Wales, with an estimated population of 15,271,425, for the week ending Feb. 20, the death-rate was 18.5. Deaths reported, 5,420; acute diseases of the respiratory organs (London) 195, whooping cough 191, diphtheria 70, measles 119, smallpox 7, scarlet fever 37.

The death-rate ranged from 8.3 in Tottenham to 27.9 in Bootle; London 17.5, West Ham 13.6, Brighton 13.6, Southampton 15.8, Plymouth 25.6, Bristol 16.4, Birmingham 22.6, Leicester 17.4, Nottingham 23.9, Liverpool 23.9, Bolton 23.1, Manchester 20.2, Bradford 21.9, Leeds 21.4, Hull 17.7, Cardiff 18.9, Rhondda 17.9, Merthyr Tydfil, 25.8, Smethwick 12.9, Newport (Mon.) 16.8.

METEOROLOGICAL RECORD.

For the week ending March 5, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

DELAYED PUBLICATION. — The strike, now happily at an end, among printers and pressmen is responsible for continued delay in issuing the JOURNAL.

SOCIETY NOTICE.

SUFFOLK DISTRICT MEDICAL SOCIETY, SECTION FOR SURGERY. — A meeting of this Section will be held at the Medical Library on Wednesday evening, April 6, at 8.15 P.M. The Society will discuss "The Treatment of General Peritonitis from Appendicitis." During the first half of the meeting the results of cases treated at the Massachusetts General Hospital will be presented and some brief papers will be read. The members of the Society will then discuss the subject with especial reference to the following questions:

What is your definition of general peritonitis?

Have you known cases of undoubted general peritonitis from acute appendicitis to recover without operation?

Should we operate on all cases however hopeless?

What can be done for a case in which operation is refused?

E. A. CODMAN, M.D.,
Secretary.

RECENT DEATHS.

JOHN KNOWSLEY THORNTON, M.B., C.M., died recently in Cambridge, England. He had for many years been distinguished for his work in abdominal surgery in London up to the onset of his illness in 1896. He was an honorary member of the American Association of Obstetricians and Gynecologists.

W. J. MCDERMOTT, M.D., a surgeon in the Civil War, and a personal friend of Presidents Lincoln and Grant, died at his home in the Borough of the Bronx, New York City, on March 13. He was seventy-three years of age, and a native of Portland, Me. He was graduated from the medical department of the University of the city of New York in 1854, and after two years of study in Europe began practice in the village of Westchester, N. Y. He was elected to the Legislature in 1860, and when in the following year the first call for troops was issued he resigned his seat in the Assembly and went to the front as surgeon of the Sixth Regiment New York Volunteers. At the end of the three months' service the regiment re-enlisted as the Sixty-sixth New York Volunteers. Dr. McDermott remained in the army throughout the war, and saw much active service. He was with Colonel Ellsworth when that officer was shot at Alexandria, and he assisted in the amputation of Gen. O. O. Howard's arm at the battle of Fair Oaks. At one time he was captured, and he was confined in Libby Prison for a season before being paroled.

MOREAU MORRIS, M.D., for many years connected in various capacities with the New York City Health Department, died on March 17. He was born at Stillwater, N. Y., on June 19, 1825, and was graduated from the College of Physicians and Surgeons, New York, in 1848. In 1866 he was appointed Health Commissioner, and in 1870 Superintendent of the New York City Health Department. From 1871 to 1884 he served as surgeon of the Seventh Regiment National Guard, State of New York.

WILLIAM FREDERIC HOLCOME, M.D., of New York, at one time widely known as a specialist in diseases of the eye and ear, died in the Presbyterian Hospital, New York, on March 17 at the age of seventy-seven years. He was born in Sterling, Mass., and was graduated from the Albany Medical College in 1850. After a course of special study in Europe he was appointed lecturer on diseases of the ear at the New York University Medical School, and in the following year, 1862, he became Professor of Diseases of the Eye and Ear at the New York Medical College. Dr. Holcome was instrumental in the founding of the New York Genealogical and Biographical Society in 1869. At the time of General Grant's last illness he was one of the specialists called in consultation.

ULTIMATE RESULTS OF SOME GYNECOLOGICAL OPERATIONS AT THE MASSACHUSETTS GENERAL HOSPITAL.

BY RICHARD G. WADSWORTH, M.D., BOSTON.

For the Division of Surgery of the Medical School of Harvard University.

During my service as surgical house officer at the Massachusetts General Hospital I had occasion to hear several adverse criticisms from some members of the medical staff in regard to the results of gynecological operations which had been performed there. These criticisms were inspired by the patients who returned to the outpatient department for treatment after operation. With the idea of reaching some definite conclusion on the subject, I have, during the past year and a half, obtained the after-history of many of the cases who had undergone operations of this class during the past five years and have had an opportunity of examining a limited number of them. Each member of the surgical staff gave me permission to use his cases, so that I have had all the cases in the three surgical services at my disposal.

The conditions included in this investigation are limited to lacerations of the cervix and vaginal outlet, displacements of the uterus, endometritis and uterine fibroids. A few cases of cancer of the uterus were also traced, but only those on whom radical operation was performed, those not having been followed which were in too advanced a stage to allow of anything but palliative treatment. Under the other heads, every case was written to which had been discharged from the hospital in good condition. In all, about 450 letters have been sent out, the patients being asked to briefly describe any trouble they may have had since the operation. About 250 responded, but in several cases the answer was too vague to give any idea as to the real condition. All the patients previously written to were asked to come to the hospital on some day during a period of ten days last summer. Ninety-five patients came and most of them were examined. The examination was unsatisfactory and valueless in many of the cases who had had lacerations repaired, owing to their having been confined since operation, but in most of the other cases a very satisfactory idea of the anatomical as well as the symptomatic result was obtained.

Thus altogether there are 58 cases in whom both the anatomical and symptomatic results have been recorded and 159 in whom only the symptomatic result has been obtained. In these cases the data have been obtained from the patient's written statement and although a more accurate and perhaps a more favorable idea of the result would have been obtained from a personal interview, it must be granted that an operation has failed in its purpose if it has not, in the opinion of the patient, relieved the symptoms for the relief of which it was performed, even if the anatomical result be perfect.

There are 53 cases in whom lacerations of the perineum or cervix or both were repaired. Twenty-three of these have been examined, but in 10, confinement had occurred since operation, so that the examination could not give an accurate idea of the result of the operation. These 10 cases will be spoken of among the others in whom only the symptomatic result was obtained.

Of the 13 cases in whom confinement has not occurred since operation, 6 have had satisfactory anatomical results, 5 have had only partially satisfactory results and 2 have had bad results.

Of the 6 cases who have had good anatomical results, 5 have been relieved of symptoms, while 1, in whom the perineum only was repaired but in whom there was also retroversion, has been somewhat helped but still has very annoying backache.

Of the 5 cases in whom I have classed the anatomical result as being only partially satisfactory, the cervix only was repaired in one and the cervix and perineum in the other 4. Of these 4 cases, 1 has been entirely relieved of symptoms, 1 has been partially relieved, while 2 have had no relief whatever. In one of these 2 last-mentioned cases there was endometritis and retroversion and the uterus was curetted a week before the lacerations were repaired. The uterus is now retroverted and there is a very incomplete perineum. The patient complains of dysmenorrhea and constipation and says the uterus comes down every evening. She considers herself no better than before operation. In the other case, the uterus was also curetted. There is a good cervix, but the perineum is poor. The uterus is in normal position. The patient complains of pain in the back and right side of the pelvis, which she says is just as bad as before operation.

The case in whom the cervix only was repaired says that before operation she never had any trouble with her catamenia. Since then, however, she has had a feeling of pressure in the head, often accompanied by nausea and palpitation for three or four days before the period. These symptoms pass off with the appearance of the flow. The uterus is enlarged and tender and there is much erosion of the cervix, which, however, is intact. I have classified this case as partially satisfactory anatomically, because although the laceration of the cervix has been successfully repaired it seems probable from the symptoms that the cervical canal was too tightly closed.

In the 2 cases of bad result, both cervix and perineum were repaired. One of these was seen two years after operation. The perineum was torn to the sphincter and the cervix was occupied by a hard nodular growth, the size of an English walnut, suggesting fibroid. In the other the operation was entirely unsuccessful and the lacerations were again repaired last April, at the City Hospital, five years after the first operation. Neither patient received any relief of symptoms.

Thus in the 6 cases of good anatomical result, 5 have been cured of symptoms, while 1 has been partially relieved. Of the 5 cases of partial anatomical success, 1 has been cured, 1 has been partially relieved and 3 have had no relief. Of the 2 cases of anatomical failure, neither have received any relief of symptoms.

Beside these 13 cases, there are 40 cases in whom the cervix or perineum or both were repaired, and who have been heard from by letter. Combining these two groups, there are 53 cases

in whom the symptomatic result is known. Fourteen or 26.4% have been entirely relieved, 25 or 47.2% have been partially relieved and 14 or 26.4% have had no relief.

Of these last 14 cases, 5 have been examined and have already been spoken of. Of the remaining 9 cases, in 1 a recto-vaginal fistula resulted from the operation and the discomfort from this has overshadowed any benefit which might otherwise have been felt. In another case there was superficial sepsis in the perineum during convalescence. This patient says she has been under a doctor's care ever since and is not at all satisfied with the result of the operation. The other 7 cases simply state that they have been no better since operation and a few say they are not so well as before.

There are 5 cases in whom cystocele was operated on besides other lacerations. Four of these have been heard from by letter. Two have had entire relief of symptoms and 2 have received no benefit. The fifth case, in whom a rectocele was also repaired, was seen three years after operation. There was a well-marked cystocele but the rectocele had been entirely cured. The patient had been perfectly well for a year and a half after operation, but had then caught a severe cold, immediately following which the symptoms which were present before operation, bearing-down pain and discomfort in walking, returned and have continued ever since, so that she now considers herself no better than before operation. In spite of the temporary relief in this case, the ultimate result cannot be said to be satisfactory, so that in these 5 cases of cystocele, the result has been satisfactory in only 2 or 40%.

There are 22 cases in whom endometritis was present and in whom only dilatation and curettage was done. In 17 of these endometritis was the only abnormality, while in the 5 remaining cases other lesions were also present.

Of the 17 cases of uncomplicated endometritis, 9 (53%) have had complete relief of symptoms. In 4 (23.5%) there has been partial or temporary relief, while the remaining 4 (23.5%) have received no relief.

Of the 4 cases which I have placed under the head of partial relief, the first, on whom the operation was performed for the relief of leucorrhea, menorrhagia and dysmenorrhea, the dysmenorrhea has not been relieved, but the leucorrhea is very much better and the periods are now normal in quantity. The second case, who was fifty-three years old at the time of operation, complained of menorrhagia. There was, besides endometritis, prolapse of the uterus, cystocele and lacerated perineum. She has had no catamenia since the operation but has occasional "unpleasant discharges." She wears a pessary and considers herself no better than before operation. The third case, forty-four years old, had hyperplastic endometritis. She says she was helped for a few months but that since then she has been only slightly better than before operation. The fourth case, twenty years old and unmarried, had endometritis. She says she was helped for a short time after operation but is poorly now, suffering from light-headedness and fainting sensation and constant leucorrhea.

Of the 4 cases who have had no relief, in 1 the pathological report on the uterine mucosa was glandular hyperplasia. She says she had a severe hemorrhage on the way home and has had a slight but constant bloody flow ever since. She now considers herself worse than before operation. The second case was operated upon for backache, irregular catamenia and constant leucorrhea. Over a year after the operation she was in the same condition as before. The third case, who had uncomplicated endometritis, wrote nearly two years after operation that she had been no better. The fourth case complained of backache, headache and painful micturition. A caruncle of the urethra was cauterized after the uterus had been curetted. Three and a half years later she reported by letter that there was no relief of symptoms, and five years after operation she was seen personally by the writer. She still complained of the symptoms for which she had been operated on. Examination revealed nothing, owing to the patient's extreme nervousness and sensitiveness. No trace of a caruncle, however, could be found.

Of the 5 cases in whom endometritis was not the only abnormality, retroversion was present in all and in 1 there was also a lacerated cervix. One of these says she has had perfect health since operation, 3 have been helped but not entirely relieved and 1 says she is no better than before operation.

Of the 4 cases who have not had entire relief 1 was interviewed four years after operation. She says she has had 4 miscarriages since the operation, but in spite of that feels better than before she came to the hospital. The uterus is in retroversion but there is no endometritis. The second case, thirty-six years old, was thought to be in very early pregnancy at the time of operation. She says she did not regain her strength after leaving the hospital and was curetted again at Lynn one and a half years later on account of a miscarriage. Since then her health has been very good. When seen last summer, she had been having leucorrhea for three months. The uterus was retroverted and there was marked endometritis. The third case was operated on when forty years old. Five years later, when seen, she said she had been fairly well since the operation but not very strong. One week before I saw her she had had an abortion performed. The uterus was large and soft but in good position and there were extensive lacerations. The fourth case, who was operated on three years ago and who had had no relief of symptoms, presented when seen last summer a well-marked splanchnoptosis. The uterus, which was retroverted at the time of operation, is now in good position, but the kidneys and liver descend abnormally on inspiration and in the upright position, both kidneys descend to the crests of the ilia and the lower border of the liver is just below the umbilicus, the stomach also descending to well below the umbilicus. No mention of this condition was made in the records but it is probable that it was present at the time of operation and is amply sufficient to account for the lack of relief obtained by curetting the uterus. She has been fitted with an abdominal supporter, but I have not been able to find out whether or not it has given any relief.

Thus of these 22 cases in whom curettage for endometritis was done, 10 have been cured, 7 have been partially relieved and 5 have received no benefit.

There are 62 cases of retroversion. Forty-six of these were treated by ventral fixation alone,

6 were treated by ventral fixation and repair of lacerations, 4 were treated by curettage only and 6 by Alexander's operation.

Twenty-two of the 46 cases treated by ventral fixation alone have been examined. Of these 22 cases, 17 have had excellent anatomical results, 1 has had a partially successful result and in 4 the retroversion has recurred. Of the 17 cases who have had excellent anatomical results, only 4 have been entirely relieved of symptoms, while 10 have been partially relieved and 3 have had no relief. The one case in whom the anatomical result has been partially successful has had partial relief of symptoms. Of the 4 cases in whom the operation was anatomically unsuccessful, 3 have had no relief of symptoms, while 1 says she has been perfectly well since operation. Thus of 17 cases in whom retroversion has been successfully corrected, only 23.5% have been cured.

Of the 10 cases of excellent anatomical result who have been placed under the head of partial symptomatic relief, the first case, thirty-seven years old, in whom the uterus was in retroversion and adherent to the rectum and the omentum adherent to the left ovary, was seen one year after operation. She complained of weakness after the day's work, with some backache and severe headache during the catamenia. She thought she had had a miscarriage at three months six months after operation. The uterus was in good position though perhaps rather far forward, and the cicatrix was firm. The second case, thirty-four years old, was seen three and a half years after operation. She still had a dragging backache which, however, was less than before operation. She also complained of pain in the right side after standing, which was relieved on lying down. She said she could do very little. Examination showed the uterus in good position but there was well-marked rectocele and cystocele. The third case, fifty-three years old, says her general health is improved but she still has more or less backache and occasional twinges of pain in the left side. Local treatment at the Massachusetts General Hospital a year ago gave her no relief. The catamenia had ceased six months before operation. The uterus is in good position and nothing was found to account for the symptoms. The fourth case, twenty years old and unmarried, says she is better than before operation but still complains of backache and a steady pain in the front of the abdomen. Dysmenorrhea is less severe than before operation but she has leucorrhea for a few days before the periods. The uterus is in normal position but there is a slight thickening of the left tube, which may account for the symptoms. The fifth case, twenty-eight years old and married, had had the left ovary removed six years before the uterus was suspended. She is much better than before operation but still has more or less pain in the right side. The uterus is in normal position. She is reported by her physician to be moderately hysterical and introspective, a type of patient in whom complete cure is hardly to be hoped for. The sixth case says she was well for six months, when after hard work she had steady abdominal pain for one week and since then has had the same pain occasionally. She now complains of getting tired very easily. The uterus is in good position but there is a slight cystocele. In the seventh case, thirty-nine and married, tucks had previously been taken in the round ligament without correcting the retroversion. One year later the uterus was suspended and a ventral hernia resulting from the former operation repaired. The hernia recurred in six weeks and nine months later it was again repaired, the uterus being found suspended by a fibrous cord about three inches long. The hernia had not recurred when I saw her two and a half years after the last operation and the uterus was in good position. She said she was perfectly well except for a burning sensation in the wound after working. In the eighth case, twenty-seven years old and married, a cystic ovary was removed at the time the uterus was suspended. She has been much better since operation but still has some backache. The uterus is in good position but there is a hard insensitive mass the size of an egg low down on the right side of the uterus which seems like a fibroid and which is presumably the cause of the persistence of the backache. The ninth case, thirty-three years old, complained chiefly of dysmenorrhea before operation. This has not been at all relieved but she says she has less backache between the periods than before. The uterus is in good position but there is a fibroid the size of an English walnut on the posterior surface of the uterus and slight thickening and tenderness of the left tube. The tenth case, fifty-five years old, wrote three years after operation that she felt much better for the operation but still had to wear a support. Examination one year later showed the uterus to be in excellent position.

Of the 3 cases who have had successful anatomical results but who have received no relief of symptoms, the first, thirty-four years old and unmarried, was operated on three and a half years ago. She says she has never been as strong since, as before, the operation. The catamenia is regular but scant and as painful as before, and she feels that she has not been helped. The second case, thirty years old and married, says that the backache, leucorrhea, painful micturition and frequent headaches, of which she complained before operation, have not been relieved at all. The third case, thirty-three years old and married, complained of constant pain in the left side and leucorrhea. The uterus was retroflexed and adherent. The pain has been just as bad since operation. Five months ago she bore twins, and she is now very nervous and tired. There is a deep stellate laceration of the cervix and the perineum is badly torn but the uterus is in good position.

The one case who has been classed as showing a partially successful anatomical result was sixty-two years old and married. She is much better than before operation but still complains of backache, frequent micturition and of feeling something come down after hard work. There is a well-developed cystocele and some prolapse of the uterus, which is, however, suspended to the anterior abdominal wall.

Of the 4 cases in whom the retroversion has returned, the first, forty-one years old, says she has been perfectly well except for occasional attacks of pain and swelling in the left leg in which there was phlebitis during convalescence. The uterus is retroverted and slightly enlarged but freely movable. The second case received no relief of symptoms and was told at the hospital, six months after the operation, that she ought to have the operation repeated. The uterus is retroverted. The third case, twenty-two years old and unmarried, had an anteflexed and retroverted uterus. The uterus was straightened with a probe and curetted, and a week later was suspended to the anterior abdominal wall. She had had no relief either of dysmenorrhea or of backache. The uterus is now in the same condition as before operation. The fourth case, twenty-seven years old and unmarried, complained chiefly of dysmenorrhea before operation. There has been no relief of symptoms and she now finds partial relief by wearing a pessary.

There remain 24 cases of retroversion in whom ventral fixation only was done and in whom only the symptomatic result has been obtained. Thirteen or 54.16% of these have been entirely relieved of symptoms, 2 or 8.33% have been partially relieved and 9 or 37.5% have received no benefit.

This result is in striking contrast to that among the cases who returned to the hospital for examination, for of the 21 cases in this latter category, only 23.8% have been cured of symptoms, while in the 24 cases whose subsequent history has been obtained by letter, 54.16% say they have been entirely relieved of symptoms. This discrepancy can probably be accounted for by the assumption that, as a rule, those cases who have been cured did not care to take the trouble to come to the hospital, while those who have not been entirely relieved came in the hope of receiving some further benefit.

If the statements of those who were seen and questioned and the written statements of those who replied by letter be given equal weight, it is found that in this series of 46 cases of ventral fixation for retroversion, 18 or 39.14% have been cured, 13 or 28.26% have been partially relieved and 15 or 32.6% have received no benefit.

Of the 6 cases in whom lacerations were repaired and the uterus suspended, 3 have been entirely relieved of symptoms, 2 have been partially relieved and 1 says she has had very little relief.

Only one of these cases was examined. She is forty-eight years old. The uterus was suspended and the perineum repaired. She still has some backache but feels much better than before operation. The uterus is in good position but somewhat enlarged and there is a deep bilateral laceration of the cervix. There is a good perineum. The laceration of the cervix in this case is probably the cause of her symptoms.

Four cases were treated by curettage. One of these has been perfectly well, 2 have been partially relieved and 1 has received no relief.

Of the 3 cases who have not been cured, in the first, twenty-three years old and unmarried, adhesions of the uterus were stretched while under ether. She has been partially relieved of the dysmenorrhea for which the operation was performed. In the second case, a fistula in ano was curetted at the same time. She writes that the fistula has been cured but that she has had more or less womb trouble ever since. A second letter asking for more details has not been answered. The third case died of pneumonia six months after operation. The husband writes that she did not seem to have been helped by the operation.

Of the 6 cases who were treated by Alexander's operation, only one was examined. In this case the chief symptom before operation was menorrhagia. This became worse after operation and the uterus was curetted at the hospital six months later, the uterus then being recorded as in retroversion. Since then she has grown stronger, but when I saw her four years later she said the pain was just as bad as before and that she had had pain in the left side ever since the operation. The uterus was anterior but enlarged and pulled to the right side of the pelvis and there was some tenderness on the left side.

Two cases returned to the hospital, sixteen months and two and a half years later, respectively, with return of the retroversion. Both had ventral fixation performed with an excellent result in both. The third case writes that she felt a little better for a year after operation but that since then she has had more pain than before.

The fourth case says the operation was successful except that she cannot carry a child more than five months, she having had two miscarriages since operation. The fifth case says she has been troubled with soreness in the right side since operation, and has severe pain unless she wears a support. She probably has a hernia.

Thus symptomatic results in these 6 cases have been good in only 1 and very unsatisfactory in 5. In the one case which was examined, the original malposition of the uterus has only been changed to another form.

Seven cases of prolapse of the uterus have been traced.

Three of these were treated by ventral fixation and repair of lacerations. Of these 3 cases, 2 have been examined. One of these had a perfect anatomical result and had been perfectly well for over two years since the operation. The other was seen three years after operation, at which a cystocele and rectocele were repaired and the uterus suspended. There is a fairly firm perineum, but the cystocele has recurred and the cervix protrudes from the vagina, so that the patient has to wear a napkin. In spite of this, however, she considers herself very well except for some dragging pain on micturition. The other case in whom the perineum was repaired and the uterus suspended was heard from two years after operation by letter, in which she stated that she was very little better than before operation.

In the other 4 cases, lacerations were repaired, the uterus not being suspended. Three have been examined and in all of them the prolapse had recurred, 1 has felt somewhat better since the operation, while the other 2 have received no relief. The other case, who was heard from by letter, says she is in very good health and has trouble with the uterus only when lifting heavy weights. Thus in 3 cases of prolapse of the uterus, repair of lacerations and suspension of the uterus has been entirely successful in 1, and has given only slight relief in 2, while in 4 cases repair of laceration without suspension has given nearly complete relief in 1, slight relief in 1 and has entirely failed in 2.

There are 18 cases of procedentia. Nine of these were treated by ventral fixation and repair of lacerations. Of these 9 cases, 4 were examined and in all but one the procedentia had returned soon after operation. In this one case the uterus was suspended and the perineum and a cystocele were repaired. The uterus is now

adherent to the abdominal wall, but the cervix is just within the vaginal outlet and there is a large cystocele. The patient has not been relieved of symptoms, still complaining of pain and a dragging sensation in the pelvis.

The other 5 cases have been heard from by letter. One says she has "got along wonderfully well," which probably means that the uterus has been restored to its normal position; 3 say that they are better than before operation, but still feel as though the uterus might descend if they are not very careful; and in the fifth case the trouble became as bad as ever a few weeks after operation.

Thus in 9 cases of procedentia treated by ventral fixation and repair of laceration, there has been entire symptomatic relief in only 1, and partial relief in 3, while of the remaining 5 cases there has been no relief, the procedentia having recurred in 4 of them.

Four cases were treated by ventral fixation alone. None of these have been examined. Three say they are just as bad as before operation, while one has been perfectly well and had a successful confinement two years after operation.

Two cases were treated by Alexander's operation and repair of the vagina. In both the procedentia has recurred and neither has been helped in any way. One has a double inguinal hernia, doubtless as a result of the operation.

In one case the perineum only was repaired. This case wrote over two years after operation that she was somewhat better but had to insert a sponge to keep the uterus from protruding when on her feet.

In two cases vaginal hysterectomy was performed and the vaginal outlet repaired. One wrote four years later that she then had the same trouble as before, while the other, three years after operation wrote that the "cushion of the bladder" came down somewhat and that she also had leucorrhea but that otherwise she felt very well.

In summing up the results in these 18 cases of procedentia, it is found that of 9 cases treated by ventral fixation and repair of lacerations, only 1 has been cured, 4 have been relieved to some extent and in 4 the procedentia has recurred. Of 4 cases of ventral fixation alone, 1 has been entirely relieved, while in 3 the condition has recurred. Repair of the perineum in 1 case has given only partial relief, and Alexander's operation has given no relief whatever in 2 cases. Vaginal hysterectomy with repair of the vaginal outlet has given no relief in 1 case and partial relief in the other. Thus in these 18 cases of procedentia only 2 (11.1%) have been cured, 6 (33.3%) have been partially relieved and 10 (55.6%) have been in no way benefited by the operation.

Fifty cases of uterine fibroid have been followed. In 42 of these supravaginal hysterectomy was performed, in 5 myomectomy and 3 were discharged without operation.

Twelve of the cases of hysterectomy were examined. Eight of these have had perfect anatomical results and all but one say they have been perfectly well. This one case was perfectly well and strong for three years after operation except for mild symptoms of the menopause, but for the last two years she has had pain in the right side of the pelvis, which was the location of the pain before operation. Examination showed nothing to account for it.

Of the other 4 cases who were examined, 2 have endometritis and vaginitis, which according to their statements has been present since operation. Of the other 2 cases, 1 has a hernia in the scar and there is a hard tumor, which feels like a fibroid, about the size of an English walnut, in the left side of the pelvis. She feels, however, perfectly well, complaining only of occasional headache. In the other, there is a smooth, rounded bony tumor on the inner surface of the pubes on the left side which is entirely insensitive to touch but is the seat of occasional sharp twinges of pain. A fibrous band extends from the tumor to the cervix, which is, however, perfectly free except for this. The patient says she first felt the tumor six months after operation and that it has been slowly growing during the four and a half years which have elapsed since then. She feels otherwise perfectly well.

In discussing the symptomatic results of these cases of hysterectomy for fibroid, I shall leave out of consideration the symptoms arising from artificial menopause, as these will be considered separately.

Of the 42 cases of this series, including those which have been examined, 33 (77.5%) have been perfectly well since operation and the other 9 cases have had more or less trouble. Five of these 9 cases have been described in speaking of the anatomical results. Of the other 4 cases, 1 had a hernia in the scar and vaginal inflammation and piles which had not been helped by local treatment at her home. Last April the hernia was repaired and the hemorrhoids cauterized at the Massachusetts General Hospital, with what result I have been unable to ascertain. The remaining 3 cases have complained of general weakness and nervousness but have had no local symptoms referable to the operation. In view of the fact that both ovaries were removed in these 3 cases, it is probable that the nervous symptoms are due to the menopause, and that they are, therefore, only temporary. Hence the results may be considered satisfactory. Thus the total of cases in whom the result has been satisfactory is swelled to 36 or 85.7%.

In regard to the effect of leaving one or both ovaries in a hysterectomy for fibroid, in avoiding the symptoms of the artificial menopause, data have been obtained in only 28 cases, because many patients have not given any information as to nervous symptoms following operation and have not answered later letters containing specific questions and because in the records of 7 cases I can find no clew to show what was done with the ovaries.

Of these 28 cases, in 23 both ovaries were removed. Twenty-one of these 23 cases have had moderate or slight symptoms, such as flush-

ing, giddiness, chills or palpitation. In the other 2 cases there have been no symptoms. One of these was fifty-four years old and had flowed only once in the six months before operation, so that it is probable that the climacteric was well established when the ovaries were removed. The other case was thirty-seven years old. There was a large fibroid extending to above the umbilicus. Her periods had been regular and normal up to three months before operation. She skipped the next period and since the last one, which came at its regular time, she had been flowing constantly. She writes, three years after operation, that she has been perfectly well and has had no nervous symptoms whatever. It would seem probable from this that the irregularity in the catamenia before operation was due to the menopause rather than to the presence of the fibroid.

Of the 5 cases in whom one or both ovaries were left, 3 have had typical symptoms of the climacteric. These cases were forty-two, forty-three and forty-six years old. All three had had menstrual irregularity before operation, and this in conjunction with their ages leaves little doubt that the menopause was beginning at the time the ovaries were removed. Whether or not the nervous symptoms were less severe than they would have been if both ovaries had been removed cannot, of course, be known. The fourth case was forty years old, and the catamenia was normal up to the time of operation. One ovary was left. She writes that she has had no typical symptoms of the menopause but has had chills accompanied by malaise and headache every month for three years. There has been no flow, but she has associated these symptoms with the catamenia on account of their regularity. She says she has not been so strong or "ambitious" since the operation. It is hard to see how any good has been done in this case by leaving an ovary. The fifth case, forty-five years old at operation, had flowed for ten days every two weeks for the previous ten years. There was a fibroid the size of a large egg and supravaginal hysterectomy was done, both ovaries being left. She writes, three years after operation, that she has been perfectly well and has flowed regularly, though much less profusely, ever since. She has had no nervous symptoms whatever. This, then, is the only case in which distinct good has been attained by avoiding castration, and the result is the more interesting as the patient was at the age when the menopause was to be expected.

These statistics, although too few to afford ground for any comprehensive conclusion, are reported because they seem to show pretty definitely, in spite of the exception just described, that in patients over forty years of age little benefit is to be derived from leaving an ovary and also because they show that sometimes in cases considerably younger than the usual age at which the menopause is to be expected, no symptoms follow complete castration.

Of the 5 cases of fibroid on whom myomectomy was done, 4 have been perfectly well during periods varying from two to six years after operation. The fifth case writes that she has not been in good health and suffers from backache. She says that her doctor thinks there may be another tumor growing.

Of the 3 cases who were not operated on, one, aged thirty-nine, had a fibroid the size of a cocoanut. It was not removed on account of the absence of symptoms and the history of Graves' disease. She wrote about four years after leaving the hospital that she felt poorly for eight months after leaving the hospital but that since then she has been in good health. She thinks the tumor is growing very slowly. It would be of interest to know whether the menopause has occurred, as this might account for the improvement in her condition, but she makes no mention of her catamenia and a second letter has not been answered.

The second case, forty-three years old, had a large fibroid. Hysterectomy was advised but refused. Three years later the patient reported that she felt much better. Up to a year before she had had a constant bloody vaginal discharge, but since then, the periods have been regular and the flow profuse but lasting only five days. There is now a constant watery discharge but without blood. There are no symptoms except occasional pain in the region of the left ovary. The fibroid now extends nearly to the umbilicus. It is freely movable and without tenderness. The patient says she does not think it has increased in size during the last three years.

The third case is now fifty-three years old. She was at the hospital four years ago with a large fibroid, twice the size of a child's head and adherent behind and laterally. The patient declined operation on account of the lack of symptoms. When seen last summer she said she had had no trouble since she left the hospital. Menstruation had ceased over two years ago and she had had no vaginal discharge since then until the last month, when she had noticed slight leucorrhea. There was a large fibroid reaching nearly to the umbilicus which seemed to be adherent. She said she had been enjoying better health since the menstruation ceased than for the last twenty years. Evidently, in this case, the improvement in the general condition has been due to the menopause.

Thus in none of these 3 cases has any ill effect resulted from not having removed the fibroid. They were all near the age of the menopause, and we know this has occurred in one case. In the other two it is probably about to occur.

Twelve cases of cancer of the cervix or body of the uterus on whom radical operation was performed and who left the hospital in good condition have been traced. Five of these cases have been examined, 4 have been perfectly well and show no sign of recurrence two and a half, four and a half, five and five and a half years after operation, respectively. The fifth case, three and a half years after operation, shows a slight indefinite thickening on the left side of the

pelvis, entirely free from the vault of the vagina, which shows a perfectly normal scar. There are no symptoms whatever. It is impossible to say whether this thickening is recurrence or not.

In 5 cases, recurrence and death occurred within three years. Of the other 2 cases, 1, operated on a little over two years ago, is perfectly well and has no pain nor vaginal discharge. The other, five years after operation, said she was perfectly well and had no vaginal discharge until two months before I saw her, when she had had a slight show after lifting a heavy weight. She refused examination, without which it is of course impossible to know whether or not this slight flowing was due to beginning recurrence.

Thus of 12 cases of radical operation for cancer, in 5 recurrence and death occurred within three years and in 3 cases there was no sign of recurrence four and a half years or more after operation. Of the other 4 cases, the time since operation is too short to give any idea as to the probable outcome in 2 and the evidence is inconclusive in the other 2. It may, therefore, be said that cure has been obtained in 3 cases, that the operation has failed in 5 and that the result is still uncertain in 4.

In summing up the results of this investigation, the following conclusions have been reached:

The anatomical results of repair of lacerations of the cervix or perineum, or both, in 13 cases have been satisfactory in 46%, partially satisfactory in 38.5% and entirely unsatisfactory in 15.5%. The symptomatic result in 53 cases has been entirely satisfactory in 26.4% and partially satisfactory in 47.2%, leaving 26.4% in whom there has been no relief. Of 5 cases in whom cystocele was repaired, there has been a satisfactory symptomatic result in only 2 or 40%.

Curettage for endometritis in 22 cases has given complete symptomatic relief in 45.5% and partial relief in 31.8%, the remaining 22.7% having received no benefit.

Ventral fixation for retroversion in 22 cases has been anatomically successful in 77.3%, partially successful in 4.6%, and has failed to cure the displacement in 18.1%. In spite of this satisfactory percentage of anatomical cure, only 23.5% of these 22 cases have received satisfactory symptomatic relief.

The symptomatic results in 46 cases of ventral fixation, including the above, have been entirely satisfactory in 39.1%, partially satisfactory in 28.3% and unsatisfactory in 32.6%.

Of 6 cases of ventral fixation with repair of lacerations, 50% have been cured, 33% have received partial relief and 17% have not been helped.

Of 6 cases of Alexander's operation only 16% have been cured, while the remaining 84% have received no benefit.

Of 4 cases treated by curettage alone, 25% have been cured, 50% have been partially relieved and 25% have not been helped.

Taking all these cases together we find that in 63 cases of retroversion, the symptomatic relief has been complete in 37% and partial in 27.5%, while in 35.5% there has been no relief.

Of 7 cases of prolapse, in 3 ventral fixation and repair of laceration was done, giving entire symptomatic relief in 1, partial relief in 1 and no relief in 1, while in 4 cases repair of lacerations without ventral fixation has given complete relief in 1, partial relief in 1 and no relief in 2,

		Anatomical Result.							Symptomatic Result.

	Ventral Fixation and repair of lacerations	1	100					1	3	50	2	33	1	17	6	
	Curettage								1	25	2	50	1	25	4	
	Alexander's operation			1	33.3	2	66.6	3	1	16			5	84	6	
Prolapse	Ventral fixation and repair of lacerations	1	50			1	50	2	1	33.3	1	33.3	1	33.3	3	7
	Repair of lacerations					2	100	2	1	25	1	25	2	50	4	
Procedentia	Ventral fixation and repair of lacerations			1	25	3	75	4	1	11.2	4	44.4	4	44.4	9	18
	Ventral Fixation								1	25			3	75	4	
	Repair of Perineum										1	100			1	
	Alexander's operation												2	100	2	
	Hysterectomy and repair of lacerations										1	50	1	50	2	
Fibroid	Hysterectomy	8	66.6	4	33.3			12	33	77.5	9	22.5			42	50
	Myomectomy								4	80	1	20			5	
	Not operated								3						3	
Cancer	Pan-hysterectomy	No recurrence 4½ years or more after operation 3				Recurrence and death 5			Uncertain 4							

a total of entire relief in 28.6%, partial relief in 28.6% and no relief in 42.8%.

Of 18 cases of procedentia, in 9 ventral fixation and repair of lacerations have given entire symptomatic relief in 11.2%, partial relief in 44.4% and no relief in 44.4%. In 4 cases ventral fixation alone has given entire symptomatic relief in 25% and no relief in 75%. Alexander's operation has failed to give any relief in 2 cases, hysterectomy with repair of lacerations has given partial relief in 1 case and no relief in 1 case, and repair of the perineum has given partial relief in 1 case. Taking these 18 cases together, 11.1% have been entirely relieved, 33.3% have been partially relieved, while 55.6% have received no benefit.

Of 42 cases of hysterectomy for fibroid, 77.5% have been entirely relieved, while the remaining 22.5% have been only partially relieved. In 3 of the cases of partial relief, the trouble since operation has been slight and probably wholly dependent on the artificial menopause — so they may be classed as satisfactory. Thus 85.7% of these 42 cases have shown satisfactory symptomatic results.

The anatomical results in 12 cases of hysterectomy have been perfect in 66.6%, while the remaining 33.3% show no serious defect.

In regard to the avoidance of the symptoms of the artificial menopause by leaving an ovary in hysterectomy for fibroid, these cases show that little benefit is to be expected in cases over forty years old.

Of 5 cases of myomectomy, 80% show entire symptomatic relief, while in the remaining 20% there has been partial relief.

Three cases of fibroid, discharged without operation, have all been perfectly well for over three years.

Of 12 cases of cancer of the uterus on whom radical operation was performed, 3 show no sign of recurrence four and a half years or more after operation and may, therefore, be considered as probably cured. In 5 cases recurrence and death occurred within three years, while in the remaining 4 cases the result is still doubtful.

EYE-STRAIN CONSIDERED AS A FACTOR IN THE PRODUCTION OF LATERAL CURVATURE OF THE SPINE (PRELIMINARY COMMUNICATION).[1]

BY HENRY W. KILBURN, M.D., BOSTON,
Ophthalmic Surgeon to the Carney Hospital.

EVERY ophthalmologist is familiar with the fact that astigmatic patients, when one or both axes are oblique, and patients having vertical heterophoria, are apt to tilt the head to one side in order to obtain clearer vision. Also, there have been reported some cases of torticollis in which there has been a marked improvement in attitude after correction of the refractive error and relief of any existing vertical heterophoria. It has been my lot to see a number of cases of lateral curvature of the spine in which eye-strain seemed to me to play a part in producing the condition. In two of these cases there was a progressive myopia, and not only did relief from eye-strain seem to cause a marked improvement in attitude, but, when the curvature had been corrected by appropriate exercises, the myopia stopped increasing. Also, in one of these two cases the vision improved to an unusual degree after correction of the spinal curvature and improvement of the general nutrition.

The cases are too few in number to permit of dogmatizing on the subject; but I think that the results obtained justify my belief that there is, in some cases, at least, a connecton between eye-strain and spinal curvature. I will describe briefly three of the cases. They may be taken as typical ones.

CASE I. Girl aged eleven. I first saw her Aug. 28, 1901. Complained of occasional blurring of print, and of frequent frontal and supraorbital pain. Carried her head tilted to the left. Compound hypermetropic astigmatism, Axis 90°, O.D.; Axis 75°, O.S. Corrective lenses were ordered for constant use. Nov. 20, 1902, head not tilted to the left as much as at first visit, but still tilted somewhat. Noticed that the patient sat in a slouching position, and seemed unable to hold herself erect. Referred the case to Dr. R. W. Lovett for correction of faulty attitude. Nov. 24, Dr. Lovett reported "a left curve" of the spine, "which carries her head and body to the left of the vertical." He also reported a "slight stiffness," "showing that the curve is of some duration," and stated that, in all positions the patient bent farther to the left than to the right. May 6, patient stands correctly.

CASE II. Girl aged eight. I first saw her on May 31, 1894. The mother stated that the child winked constantly when she read. Examination of the refraction with a mydriatic showed the following conditions:

R.V. = 6/4— c + 0.25 Sph. ⌒ + .25 Cyl., Ax. 0°.
L.V. = 6/4— c + 0.25 Sph. ⌒ + .25 Cyl., Ax. 0°.

At the post-cycloplegic visit, the cylinders only were accepted, and these were ordered for constant use. Sept. 18, 1896, the child says she can now see better without the glasses than with them. A mydriatic was again used, and the following refractive condition was found:

R.V. = 6/4— c — 0.25 Sph. ⌒ —0.25 Cyl., Ax. 0°.
L.V. = 6/4— c — 0.25 Sph. ⌒ —0.25 Cyl., Ax. 0°.

In other words, the child had become myopic. There was also an exophoria of 1.5°. Advised her withdrawal from school for a year. The patient held her own until March, 1898, when I found an increase of myopia of 0.5 D., O.U. In the following November, I found a further increase of 0.25 D., O.U. There was no change in the astigmatism or the vision. There was, however, a right hyperphoria of 1.5°. Also, I noticed that the patient tilted her head to one side. I referred the case to Dr. Lovett, who found a lateral curvature of the spine. In addition to the treatment prescribed by Dr. Lovett, I ordered exercise prisms for the correction of the hyperphoria. With appropriate exercises for the trunk muscles, the spine became straight, and the myopia stopped increasing. Also, on Sept. 23, 1899, there was barely 0.5° of hyperphoria.

CASE III. Girl aged twelve. Was brought to me Nov. 19, 1900. The father stated that she held her book very near when she read, and that she had worn glasses for near-sight for several years. The head was tilted forward and sideways. Examination with a mydriatic showed the following conditions:

[1] Read before the New England Ophthalmological Society, March 8, 1904.

R.V. = 6/8 c — 4.50 Sph. () —0.37 Cyl., Ax. 0°.
L.V. = 6/12 c — 1.50 Sph. () — 3.00 Cyl., Ax. 25°.

There was also a left hyperphoria of 2°. As the accommodation was excellent, the full correction was ordered for constant use. On May 4, 1901, the vision and refraction remained unchanged, and the patient had no discomfort of eyes or head; but the hyperphoria was still present. The head was now held erect. Nov. 30, 1901, the patient complained of ocular pain. The vision was unchanged, but there was an increase of myopia of 0.25 D., O.D., and 0.50 D., O.S. I ordered the full correction, combined, O.S., with a prism of 2°, base down. Feb. 8, 1902, the patient had no discomfort, but the myopia had increased 0.75 D., O.U., and the patient tilted head and body slightly to the left. Ordered the patient to be taken out of school, and referred the case to Dr. Lovett, for correction of faulty attitude. He reported a left lateral curvature. With appropriate exercises, the curvature soon disappeared, and the patient held head and body erect. Not only was there no further increase of myopia, but, what was still more surprising, the vision began to improve, until on Jan. 6, 1903, the right vision was 6/5—, and the left vision was 6/6—.

I have seen several other similar cases where similar results were obtained; but the three cases described above may be taken as typical. I feel strongly that, in these cases, eye-strain, by inducing a faulty attitude, acted as an indirect factor in the production of the spinal curvature. I think, also, that, when the curvature had become established, the stooping position caused the patients to approach the eyes too near to the desk, and caused the myopia to increase. Thus, both the myopia and the scoliosis acted and reacted upon each other in a vicious cycle, just as do eye-strain and neurasthenia. The patients were all growing girls, *i. e.*, patients whose bodies were in the plastic condition of adolescence. All of them had poor muscular development, and the rapid increase of body weight had contributed to the vicious result, being proportionally far greater than the increase of muscular strength.

In Case I, while the correction of the refractive error evidently caused a less faulty position of the head, it was not able to do more than this until the stiffness of the spine had been relieved, and the muscles strengthened by exercises, so that they could properly support the trunk.

In Case II, my theory is that myopia caused the patient to lean forward over her desk at school, and that, supporting her body by her left elbow, her position was such as to cause a dropping of the right shoulder, and a curve of the spine to the right, with the convexity to the left. It is possible that this position may have caused the hyperphoria. At all events, when the faulty attitude was corrected, the hyperphoria disappeared.

In Case III, I think that the hyperphoria caused the patient to tilt the head and body to the left.

In Cases II and III, I think the myopia stopped increasing because, when the trunk muscles had been strengthened, the patients were able to sit erect without difficulty, and ceased to bend forward over the desk as formerly. In all the cases, correction of the eye-strain was not alone sufficient to remedy an already established spinal curvature.

Dr. Scholder of Lausanne, in a paper entitled "Die Schulskoliose und deren Behandlung,"[2] found a close relationship between myopia and scoliosis. He states that the amount of myopia found in such patients was in direct proportion to the amount of scoliosis. His statistics are based upon an examination of 2,314 school children, 571 of whom had a spinal curvature. The paper is a very exhaustive one and very interesting, and well repays a careful reading. Dr. Scholder's statistics have confirmed me in my opinion that there is often a direct relationship between eye-strain and spinal curvature. At all events, I think the idea deserves careful investigation.

SUPERNUMERARY BREASTS AND NIPPLES, WITH REPORT AND PHOTOGRAPH OF A CASE.

BY ERNEST BOYEN YOUNG, M.D., BOSTON.

Second Assistant Visiting Physician for Diseases of Women, Boston City Hospital; Assistant in Gynecology, Harvard Medical School.

THE occurrence of supernumerary breasts and nipples has been recognized for many centuries; as in the time of the ancient Greeks, Diana was represented with multiple breasts as a symbol of plenty; while the mother of the Roman emperor Severus is said to have acquired her name, Julia Mammæa, from this deformity. In more recent times, the unfortunate queen Anne Boleyn is reported to have presented the anomaly of three breasts.

As the subjects of supernumerary breasts and nipples are so closely allied, they are considered together in the present brief article.

CASE. A. B., thirty-eight years, married, was admitted to the Gynecological Service at the Boston City Hospital where I saw her with Dr. C. M. Green. About four weeks previous she had given birth to her fifth child by normal labor, but on the third day had chills and fever, and had not been well since. The child had nursed up to time of entrance and both breasts contained milk.

On the left breast about 6 cm. below the main nipple was another somewhat smaller but well formed, from which milk exuded almost as readily as from the upper. The patient said that milk always flowed from the lower nipple whenever the baby nursed upon the upper. While quite large at the time of entrance, it became reduced in size and appears in the photograph considerably smaller than when first seen. No other member of the family had any such deformity.

MEASUREMENTS.

Main areola	3.5 cm. in diameter.
Main nipple	.2 cm. in diameter.
Accessory areola	.3 cm. in diameter.
Accessory nipple	.1 cm. in diameter.
Distance between nipples	.6 cm.

[2] Archiv. f. Orthopädie, Mechanotherapie, u. Unfallchirurgie. I Band, 3 Heft, 1903.

Although often mentioned by the older writers, Meckel [1] was the first to attempt to explain these anatomical curiosities from an embryological standpoint, and following him, Darwin [2] and Bartels [3] called attention to them in connection with the theories of evolution. The references to the writings of the older physicians will be found in the very complete article of Leichtenstern.[4] According to many observers anomalies of this nature are not uncommon, appearing in men quite as often as in women; in fact both Bruce [5] and Leichtenstern declare them twice as frequent in the former. Bruce found 60 in 3,956 examinations (1.56%), while Leichtenstern places the proportion at 1 in 500, including both sexes. Leichtenstern, in 1878, collected 92, adding to them 13 of his own; Hartung [6] in 1885, 66; Puech,[7] in 1876, 77 in France alone; and Bardeleben,[8] among recruits, found one man in seven presenting one or more accessory nipples.

From external appearances these anomalies may be roughly divided into two general types according as multiple nipples occur upon what appears to be one breast (polythelia) or when nipples appear on other parts of the body apparently connected with a certain amount of isolated breast tissue (polymazia). Both of these terms, however, have been used interchangeably.

Usually the supernumerary breasts and nipples are small and poorly developed, but occasionally one or more of them may attain a considerable size and give milk freely. Gardeur [9] mentions a mulatto woman with four milk-giving breasts, and Bartholinus [10] a Danish woman with three. They increase in size during pregnancy and oftentimes the first sign of the nature of these nipples, which have often been mistaken for nævi, comes with the physiological activity of the underlying glandular structures. Occasionally breast tissue has also been known to exist in the axilla and swell with each pregnancy; although neither ducts nor nipple had developed. Goldberger [31] reports one and Leichtenstern three such instances.

Although usually found along two lines which run from the anterior borders of the axillæ to the pubes and rather inclined to symmetrical arrangement, they are often irregularly placed. Percy [11] refers to a case with five breasts, the fifth being in the median line, and in the writings of Fortunius Licetus (1668) [12] is a picture of such an arrangement (figured by Neugebauer). Accessory breasts are also reported on the labia majora (Hartung), on the outside of the thigh (Robert [13]), over the acromion (Klob [14]), on the back (Duval), twice in the walls of dermoid ovarian cysts (Haffter [30]); in the groin (Ahlfeld [15]) and in front of the ear (Barth [32]). In Robert's case the woman nursed a child from the breast for thirty months, and in one published by Jussieu [16] a gland in the groin was occasionally suckled by the infant. Neugebauer [17] reports the highest number of supernumerary nipples in a single individual and in his article, the reference to which is given, will be found a reproduction of a photograph of his case showing ten nipples of various sizes. In the article of Quinquaud [18] is also a most excellent photograph of axillary breasts.

Heredity appears to have a certain influence; as Hirst [19] and Robert have both seen polymazia and Woodman [20] supernumerary nipples in mother and daughter, while Lousier [21] speaks of a woman who, having but one breast, transmitted the deformity. Supernumerary nipples are found upon the same breast. Hollerius [22] mentions one with two nipples, each of which secreted milk in abundance and in our own case milk spurted from the lower nipple, although only the upper was suckled by the infant. They have been found in all positions around the chief nipple, but are usually small and situated below in over 90% of the cases: usually upon the line mentioned.

The questions as to whether the accessory nipples are connected with the main breast or with separate collections of tissue; as to the nature of the underlying glandular structures; as well as the cause of such anomalies, have been

variously answered by different writers. Förster [23] explains multiple nipples upon the same breast as separate openings for different bundles of milk ducts and in our own case this view seems quite probable. Ahlfeld considers it quite natural that milk-giving glands are found in the axilla, as the lymphatic glands of this region are connected with the breast; but Neugebauer thought his famous case one of true mammæ accessoriæ.

As to the manner in which the transplantation takes place, widely divergent opinions prevail. has evidently the greatest number of adherents among the writers upon these subjects and certainly offers the most satisfactory explanation for the appearance from time to time of these rather interesting deformities. For the anomalous position of such as occur on the outer side of the thigh and on the back, some further explanation must be sought and possibly in these very rare cases the transplantation theory of Ahlfeld may be correct. As regards the nipples which appear as accessories of the main nipple of the breast, the theory of Förster offers an adequate explanation and one in keeping with the embryological development of the organ. Neoplastic changes, according to E. Martin,[27] are so rare in supernumerary breasts that he finds only one doubtful report in medical literature beside his own. At the same time he considers that the small "lobuli aberrantes" about the breast should be watched and removed if they

variously answered by different writers. Förster [23] explains multiple nipples upon the same breast as separate openings for different bundles of milk ducts and in our own case this view seems quite probable. Ahlfeld considers it quite natural that milk-giving glands are found in the axilla, as the lymphatic glands of this region are connected with the breast; but Neugebauer thought his famous case one of true mammæ accessoriæ.

As to the manner in which the transplantation takes place, widely divergent opinions prevail. Ahlfeld [15] says that by pressure of the amnion part of the cells become separated, and, fastened to the amnion, are transplanted to other portions of the surface of the body. Förster and E. Hartung hold the same idea as to portions of tissue becoming separated, but express no opinion as to the manner of its occurrence. According to Leichtenstern many previously considered accessory breasts the result of aberration of the milk ducts probably from the work of Meckel and Owen. St. Hilaire sought to trace polymazia back to the general plan of the lower mammals and Darwin thought it due to atavism. Leichtenstern, Neugebauer, Billroth and many others consider it a reversion to the previous types of our ancestors. Perls, [24] on the other hand, has strongly combated the view of atavism and Duval [25] explained the axillary, as well as those appearing upon the back and acromion, as modifications of the sebaceous glands. Champneys [26] has also advocated this view. However, Virchow [29] remarks that it is not so easy to tell with which one is dealing as their development is so similar. E. Martin [27] believes that certain parts of the breast tissue are cut off from the mamma and lie near to the true breast. These are often felt as tumors, and swell with pregnancy and menstruation, but are not true accessory breasts. They may even appear in the axilla. Flechsig [28] held much the same view for this class of cases and Hartung gave to these structures the name of "mammæ accessoriæ spuriæ."

The proposition has been advanced that females with supernumerary breasts are more liable to multiple pregnancies, but there is no reason to believe that such is the case, as only two appear in Leichtenstern's series of 70 females.

The theory of reversion to some previous type has evidently the greatest number of adherents among the writers upon these subjects and certainly offers the most satisfactory explanation for the appearance from time to time of these rather interesting deformities. For the anomalous position of such as occur on the outer side of the thigh and on the back, some further explanation must be sought and possibly in these very rare cases the transplantation theory of Ahlfeld may be correct. As regards the nipples which appear as accessories of the main nipple of the breast, the theory of Förster offers an adequate explanation and one in keeping with the embryological development of the organ. Neoplastic changes, according to E. Martin, [27] are so rare in supernumerary breasts that he finds only one doubtful report in medical literature beside his own. At the same time he considers that the small "lobuli aberrantes" about the breast should be watched and removed if they are the cause of discomfort, as new growths appear at times to start in these structures. The reader is also referred to the article by Williams [33] for further information.

RING BODIES IN ANEMIC BLOOD, ADDITIONAL FORMS.

BY RICHARD C. CABOT, M.D., BOSTON.

Since my first article on the subject of ring bodies [1] I have examined in all fourteen cases of pernicious anemia in the active stages, nine of which (or 64%) showed the presence of rings more or less similar to those previously described. I have also found them in the anemia secondary to lead poisoning as well as in lymphatic leukemia. Negative results were obtained in four cases of pernicious anemia in the stage of remission, in ten cases of leukemia (six of the lymphatic and four of the myelogenous type), nine cases of severe secondary anemia from various causes and twenty-two cases of various skin diseases.

My friend, Dr. Charles E. Simon, in the latest edition of his text book on *Clinical Diagnosis*, confirms my findings and pictures.

In the accompanying cuts are shown some forms not previously illustrated and serving to increase, rather than to dissipate, my ignorance in regard to their origin and nature.

TYPHOID FEVER IN INFANCY, WITH REPORT OF A CASE COMPLICATED WITH MENINGITIS TERMINATING IN RECOVERY.[1]

BY CHARLES P. SYLVESTER, M.D., DORCHESTER, MASS.

Typhoid fever in infancy is getting its share of historians at present, and I know of no subject in pediatrics upon which there is more discordant feeling, nor one which will cause a more heated discussion among children specialists. All now admit that it does occur, but its frequency is the question upon which the disagreements arise. Holt and Northrup, from their own experiences, and from the records of the New York Foundling Hospital and Infant Asylum, claim that it is extremely rare, the former stating that he has never seen a case in a child under two years of age, while Northrup, in his many hospital autopsies, has never once found

[1] Read before the Norfolk District, Massachusetts Medical Society at Dorchester, Dec. 29, 1903.

evidence of the disease, nor do the records of the two hospitals show a single case. Griffith of Philadelphia, on the other hand, has collected 417 reported cases, some of which, however, are doubtful, owing to the absence of the Widal reaction. Morse, who has very carefully treated the subject, states that it is infrequent.

There is no doubt that infantile typhoid is much more prevalent than is generally believed, but, from the somewhat atypical symptoms, shorter duration and the teaching of authors of such eminent repute as Holt, it has neither been recognized nor looked for, but has passed under the disguise of ileo-colitis, ptomaine poisoning, broncho-pneumonia, influenza or meningitis, it sometimes closely simulating the latter disease. The fact that autopsy failed to give evidence of the intestinal lesion would not necessarily disprove its existence in infancy, however convincing such facts would be in childhood and adults, for, as I shall mention later, the intestinal symptoms are not often marked, the inflammation and infiltration of the intestinal glands not usually being severe enough to leave ulceration or to furnish diagnostic lesions for the pathologist, such complications as hemorrhage and perforation being extremely rare. Moreover, measles, scarlet fever, diphtheria, ileo-colitis or even simple diarrhea, may produce lesions of swelling, hyperplasia and fatty degeneration of the intestinal and mesenteric glands identical with those of typhoid of early childhood.

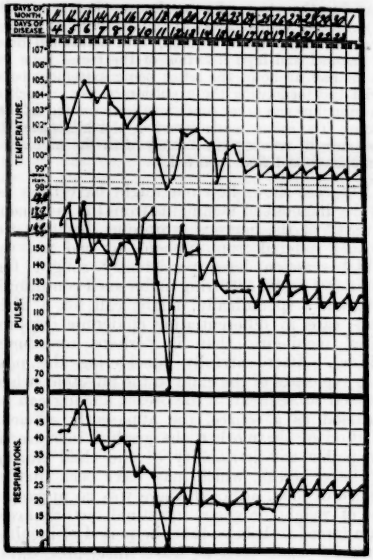
The shortness of the fever period would seem to confirm the statement as to the mildness of the intestinal condition, as the secondary fever due to the absorption of septic material from the sloughing ulcers is absent. Why infants should not be victims to the disease oftener than they appear to be I fail to understand, living as they so often do upon cow's milk modified with water, and being so susceptible to gastro-intestinal and other bacterial diseases. The physiological leucocytosis may be worth consideration as an immunizing power against the Eberth bacillus during the first two years of life. Breast-fed infants are far from being so naturally exempt as most chroniclers state, for aside from the water which the child takes, the mother, after being exposed to the disease, may excrete the bacillus from her breasts whether she be a victim to the disease or has a natural or acquired immunity. This would account for some of the sporadic cases of infancy. The case which I report below may have become infected from the breasts of the mother.

The only absolute way of differentiating between typhoid in infancy and diseases which resemble it is by the Widal serum reaction, and until this technique is employed in all cases of continued fevers no one has a right to say that the disease does not occur primarily, or as a complication, or that it is even extremely rare. Had this test been applied more since it was discovered in 1896, it is not improbable that some of the cases which Holt diagnosed as broncho-pneumonia from "prostration, cyanosis and rapid respiration," or as meningitis from the "continuance and severity of the nervous symptoms rather than by the presence or absence of single or special symptoms," might have responded beautifully to the reaction. Unfortunately the test does not occur early in the disease, frequently not before the tenth day, and often has not been found until after recovery, and no doubt death claims many which are buried under the certificate of other diseases before occurrence, unless autopsy clears up the diagnosis. In all continued fevers it should be sought for every second day until it is found, or until death or recovery takes place, and occasionally after the latter until the sixtieth day if any doubt still exists. Isolating the bacillus from the blood bids fair, when the technique is a little better developed, to differentiate the disease six or seven days before the clumping takes place. A positive paratyphoid reaction may clear up the doubt, although I find no report of this form of disease in infancy.

The period of incubation in the little ones is rather difficult to determine, owing to the small number of cases reported and to the difficulty in tracing the time of exposure and the first appearance of the symptoms. However, it would seem to be about the same as in later life, or longer, according to the susceptibility of the infant.

The bacillus, besides gaining entrance by the usual methods, may pass in utero, through the placenta, directly into the child's blood, generally causing its death, although not invariably.

Symptoms.—The onset is usually more abrupt than in later life, and the nervous symptoms are usually marked throughout the disease, much more than the intestinal. Vomiting is common; epistaxis is infrequent; bronchitis is generally present with its usual signs; diarrhea is the rule, though many cases are constipated; tympanitis, with gurgling in right iliac fossa, is usually marked and sometimes absent; and abdominal pain and splenic tenderness may be found; systolic heart murmur may be marked, and in the anemic or badly nourished may present a serious complication ere the disease ends.



The spleen, although always enlarged, may be doubtful to palpation or percussion on account of the distention of abdomen. It may be very soft and should be handled with care. Although not always found, the eruption is probably present in every case at some time, and may be very profuse. Desquamation may occur, and moderate albuminuria is present. White blood count in absence of complications will be normal for infancy, when it is higher than in later life. The gradual incline of temperature curve may not be observed, owing to the sudden onset or late observance of sickness. Thus the symptoms in severe cases anyway are to a certain extent similar to those of typhoid of childhood. They may be typical or atypical, mild or severe, and the nervous symptoms are mild or severe, but usually predominate, and with the beginning of the disease mild muscular twitching, with

retracted head or general convulsions, may occur. Even Kernig's sign may be present to apparently confirm your diagnosis of meningitis, but wait,—the enlarging spleen, the distressing distention, appearance of rose spots, and lastly, the most important and absolute diagnostic point, the Widal reaction, appears and dissipates all doubt as to the disase.

The prognosis is more unfavorable than at any other period of life, owing principally to the frequency of the serious complications. Bronchopneumonia, scarlet fever, meningitis, measles, diphtheria, acute otitis media and noma may turn the tide against the patient. The mortality of cases recorded varies from 25 to 50%. This is certainly too high, as mild cases are not so apt to be diagnosed or reported. The duration of the fever stage is ordinarily from two to three weeks, and may be even shorter in infants recovering without complications. An idea as to the treatment will be considered under the case below.

R. L., boy, six months. Mother contracted typhoid in Ohio the last of March, 1903, by drinking water from an infected well, and returned East with child, to be taken sick April 20. Nursed child until April 30, when she had temperature of 104.5°. Baby was then put on a prepared food and removed to a room on the floor below, and on May 28 was brought to the dying mother, who held his hand — which was afterward carefully disinfected — for a few minutes prior to her death. Ten days later, thirty-nine days after last nursing and just sixty days after the mother drank infected water, the baby, who was previously well, although abnormally pale, became very nervous, irritable and sleepless. Vomited on third day and had three light-greenish, watery movements.

I first saw the child June 11, the fourth day of the sickness. Extreme pallor and nervous symptoms first attracted my attention. Head was retracted and fingers and muscles of other parts were convulsive; temperature was 104°, pulse 165 and respiration 44; lungs were negative, but there was a marked systolic murmur; spleen was palpable and abdomen distended with gurgling in the right iliac fossa; pupils were regular; Kernig's sign was present, no eruption. Temperature reached 105.1° in next two days; pulse 180; respiration 52 and irregular with slight cough and mucous rales in smaller bronchi. Rose spots appeared on the sixth day in successive crops in right epigastrium, hypogastric and lumbar regions, and were present for a week. Patient was now delirious, with carphologia and other nervous symptoms intensified. Distention became greater, making percussion and palpation of spleen difficult, and discharges from the bowels were four to five daily. On the ninth day temperature had declined to 102°, pulse 150 and respiration 30. Tongue was brown, dry and cracked; cough slightly increasing. On June 17, the tenth day of disease, unmistakable symptoms of incipient meningitis appeared, followed later by others which fully confirmed the diagnosis. The skin was hyperesthetic; the child, jumping on being touched or at loud noises, would awaken screaming in pain, vomiting and refusing all food. Eyes were widely dilated, and convulsions occurred one after the other almost all night and occasionally next day, opisthotonos and stupor following with an intense drop in pulse, temperature and respiration during the next twenty-four hours, as shown on chart, the temperature

falling from 103 to 98, pulse from 176 to 60 and respiration from 30 to 7 per minute and irregular, when child was cyanosed and in deep coma with lower extremities rigidly flexed and pupils contracted and unequal. Opisthotonos, rigidly flexed legs, unequal pupils and coma remained for two days. Twitching of right side, especially leg, and later, to a less degree, the left side, and internal strabismus of right eye, remained until the eighth day of meningitis and the eighteenth of typhoid. On the twentieth day, morning and evening temperatures were practically normal, bowel discharges about normal in number and color, and slight cough, heart murmur and cyanosis, requiring constant stimulation, were still present, but improving. The serum reaction was positive on the eighteenth day of disease, although last negative was four days previous. Paratyphoid was negative; urine, examined on twelfth day, contained moderate amount of albumen. I regret that no blood count was made.

Treatment. — Ice compress was kept continually around the head until the temperature and nervous symptoms had practically disappeared. The irritable stomach was fed with milk modified and peptonized, its strength increased by the addition of one of the prepared foods. For two days of coma peptonized enemata of milk and beef juice were administered, except when the legs were too rigidly flexed to allow the insertion of the rectal tube. Brandy, five drops in the beginning every three hours, was gradually increased to one or one and a half drams every one to three hours, depending upon the degree of collapse, and was at times with digitalis, nitroglycerin and atrophin ruthlessly given, with mustard paste about the chest and actual cautery to the back of the neck. Strychnin was not used much on account of the nervousness. Oxygen was given with good effect toward the end of the meningeal symptoms, when the child was cyanotic, improving his color, soothing him to sleep and quieting his cough, which I believe

was due then to cardiac weakness. For tympanitis injections of soap and water or oil, emulsion of assafetida and turpentine were used, with occasional doses of calomel and high insertion of the rectal tube left in for half an hour, the latter being extremely beneficial and facilitating the expulsion of gas. Cracked, bleeding lips and other conditions were treated as they arose. The infant made a perfect convalescence, the first case of recovery in infancy with the meningeal complications I find reported.

The case shows how one might have been led to the diagnosis of meningitis from the increasing severity of the nervous symptoms, had not the mother suffered from typhoid, or had not the Widal reaction been persistently sought for, and a few cases, occurring under such conditions, apparently sporadically, might call for a little more care in differentiating epidermic cerebro-spinal meningitis than is perhaps sometimes utilized. After carefully considering the possible exposures of the child to the infection, when his food subsequent to the breast nursing can be excluded as a source, the apparently efficient isolation of the mother, the gradual increase in the pallor and irritability of the child during the latter weeks, which may have been due to change of food, although there was no apparent loss of weight or gastro-intestinal disturbances, I am forced to believe that the period of incubation may have been at least thirty-nine days, that the insusceptibility of the infant was overcome only after a long struggle. As, however, I saw the mother only in consultation, I am unable to vouch for the constancy of the quarantine, but if the child contracted the disease during the thirty-nine days previous to the appearance of the symptoms, more care should be used to protect the susceptible than is deemed necessary or exercised by our contemporary therapeutists.

Clinical Department.

AN ATTEMPTED SUICIDE BY ILLUMINATING GAS. [1]

BY FRANK HOLYOKE, M.D., HOLYOKE, MASS.

THE toxic results of inhalation of illuminating gas are twofold, causing in some cases simple asphyxiation; in others "an intoxication by prolonged contact with the gas, leading to a toxemia and the formation of co-hemoglobin" (E. H. Bartley).

The following case is of the second type, in the acute form, and occurred on July the first, when the roomers in an apartment house were disturbed by moaning heard in a neighboring room which had continued through the afternoon and evening until eight o'clock. They knocked at the door but were unanswered. The police were called and on breaking in the door, which was locked and corked with rags and the windows closed tightly, quite effectually preventing the escape of the illuminating gas which was pouring into the room from two open jets of the chandelier, they discovered the air unbreathable and Mr. A. C., a man of forty-four years of age, lying back in an easy chair unconscious, in a high-studded room which was 12 by 15 feet square. He was removed from the room and the windows and doors thrown open. It may be well to note that this illuminating gas is a mixture which averages, through the year, two parts coal and one part water gas, according to the state inspector's test at Holyoke.

Dr. J. C. Hubbard of Holyoke answered the call within ten minutes and found his patient perspiring profusely, his clothes being drenched with sweat; the pupils were dilated, face cyanotic, the limbs relaxed, pulse imperceptible at the wrist, but a feeble heart's action was felt, beating about 140 per minute. Respiration was very slow and gasping and the jaw had dropped — in short what appeared to be a state of collapse.

Dr. Hubbard first tried artificial respiration, which was followed by increased frequency in respiration, while $\frac{1}{30}$ gr. of sulphate of strychnia in divided doses and $\frac{1}{100}$ gr. of nitro-glycerine, during the half-hour that he was in attendance, restored the pulse to the wrist, but the doctor had little hopes of his recovery. The patient being removed to the House of Providence Hospital, I was called as medical examiner at 9.30 P.M. I found him lying in bed stripped of clothing but covered with blankets. The body was pale and cold. The arms and legs had now become cold, rigid and in a state of tetanic convulsion. The pupils were markedly dilated and did not respond to light. The breath was strong with the naphtha-like odor of gas, which did not entirely disappear until the fourth day. Temperature by rectum was subnormal 96½, which according to statistics appears exceptional. The pulse 142, respiration 32 and shallow, with spasmodic action as though snapping for breath, and a thin frothy mucus had to be wiped occasionally from between the lips.

Physical examination showed feeble heart's action and large mucus rales over both lungs. These rales cleared completely on the second day. A strong draught of fresh air passing through the room from open windows, warmth to the body and heart stimulants hypodermically were the only measures taken for immediate relief.

The normal temperature was not reached until the third day, when it rose steadily to 100⅘, the highest point reached, on the evening of the sixth day, and gradually diminished from the sixth, with slight feverish action throughout the second week. The pulse fell to 80 on the seventh day and respiration to 20. He voided urine in considerable quantity and involuntarily during the first three days. Bowels first moved by enema on the second day. Through the night of the second day he gradually regained consciousness, became quite rational and began to take liquid nourishment, though he swallowed with difficulty and cold water caused severe pain in the mouth and throat, producing a spasmodic action of the throat. He vomited his milk several times on the third day. For the first two days of consciousness he complained of great pain in his head, which was general, not localized, and also of a numbness of the limbs which continued for nearly a week.

On the morning of the second day my attention was called to a peculiar condition on the back of the shoulder blades and over the sacrum and buttocks, which parts came in direct contact with the easy chair where he was originally found sitting. These parts were thickened and brawny, bright red, hot and very sensitive as though scalded but the brawny thickening was too deep for an external burn or for a recent bed sore. The skin was not blistered, but loosened in a

[1] Read before The Massachusetts Medico-Legal Society, Oct. 7, 1903.

few days, leaving a large denuded surface which healed over very slowly and was sensitive for several weeks. Numbness of the legs disappeared in about one week's time and as this abated he suffered with sharp shooting pains in the left leg and foot, accompanied with motor paralysis of the muscles controlling foot and toes, from which he has not at expiration of twelve weeks fully recovered, though the muscles respond to the faradic current.

It was also interesting to observe the result of paralysis of the vasomotors of this leg, which, when allowed to hang from the bed, or, as in the second week, when he tried to stand up, rapidly filled with blood, the skin becoming turgid and deep purple with distended vessels until he felt faint. The right leg was unaffected, retaining its normal color. This vasomotor paralysis disappeared entirely by the sixth week and also the shooting pains in the limb.

The latest article that I have seen on "poisoning by illuminating gas" is a very clever one by Dr. Paul M. Pitcher published in the *Brooklyn Medical Journal* of May, 1903, in which he concludes that: "The toxic effects of inhaling illuminating gas are due primarily to chemical changes produced in the constituent elements of the blood, this being a substitution of carbon monoxide hemoglobin for the oxy-hemoglobin, so diminishing the supply of oxygen to the tissues. Further that the *direct cause* of most of the symptoms *is* the diminished percentage of oxygen contained in the arterial blood supplying the central nervous system" (compare Haldane, p. 443).

We may concede this effect of carbonic monoxide (the chief poisonous agent of illuminating gas) to *be* the primary cause of the paralysis of the sensory, the motor and vasomotor nerves, producing the variety of symptoms here observed, possibly also the exquisite sensitiveness of the mouth and throat to cold drinks. I am at a loss, however, to account for the peculiar *external* appearances over the buttocks and shoulders. The question naturally arises if it can be due to any local irritation from the poisoned sweat in prolonged and close contact with a surface preventing the free escape of the perspiration from those parts, or is it because the pressure, long continued, has caused a temporary emptying of the blood vessels which, being suddenly relieved from pressure at that part, react *more* strongly and fill to *excess* by reason of the *general* tendency to vasomotor paralysis, causing here such a congestion as to result in inflammation of the skin tissues? The latter supposition seems to me more plausible.

A CASE OF TRAUMATIC CEREBRAL HEMORRHAGE.[1]

BY C. A. ATWOOD, M.D., TAUNTON, MASS.

I PRESENT to your notice to-day a case of traumatic cerebral hemorrhage.

It seems to me that the case may be of interest, not only in its medico-legal relation, but surgically.

[1] Read before the Medico-Legal Society, Oct. 7, 1903.

E. M., a French-Canadian, age forty-four, was returning from the city to his home on an electric car at about 9 P.M., June 7, 1902. While the car was in motion and fearing probably that it would not stop in front of his house, he attempted to save time and distance by getting off. The result was that he was thrown into the road, striking upon the back of his head. The road had recently been repaired by filling with sand and it was soft. He got up and went to his home. A short time after he complained of not feeling very well and sent for his physician. The physician at that time found no serious symptoms. E. M.'s condition, however, became worse and the physician was again summoned, who found him unconscious and pronounced the case one of apoplexy, for which he bled him.

E. M. never regained consciousness and died at 6.40 A.M., June 8, 1902. I viewed the body and performed an autopsy at 3 P.M. There were no visible marks of violence on the body. The symptoms followed by coma before death all pointed to some acute cerebral injury. On reflecting back the scalp, beneath it and near the occipital protuberance of the occipital bone was found a blood clot. The cranium was opened and there was no fracture of the skull. The dura was tense. When opened quite an amount of cerebral fluid escaped. The sinuses and vessels of the pia and brain were full and engorged. In the frontal lobe of the left hemisphere near the longitudinal sinus was a blood clot the size of a golf ball. This was the only lesion found and caused death by cerebral pressure. Macroscopically there were no other lesions.

The theory is that the man fell forcibly on to the back of the head with sufficient momental violence to cause by contre-coup a rupture of a blood vessel in the anterior portion of the brain opposite the site of the original injury.

The Court asked this question: "If there were no external marks of violence and no fracture of the skull how was it possible to state that the cause of death was due to violence or the fall?" The answer was: "The man never having had any cerebral symptoms of disease before, and in this case having come on immediately or soon after an injury, with the finding of an antemortem blood clot beneath the scalp, in the region where he was struck when he fell with force, was evidence enough to consider the hemorrhage of the brain, which caused death, to be due to injury and not to previous disease, together with the fact that there was no other pathological lesion present." *The Court so ruled.*

It may not be too much out of place to mention surgically something about this case. At the present time I believe that some of our more progressive surgeons advise even in the absence of localizing symptoms, if coma and other conditions are progressive, to interfere; that is, to open the skull in the sense of an exploratory trephining. The usual rule would probably be in a case like this, if undertaken, to trephine at the seat of injury. I have thought since if this had been attempted that it would certainly have been a long hunt for the seat of injury.

Medical Progress.

RECENT PROGRESS IN GYNECOLOGY.

BY W. L. BURRAGE, M.D., BOSTON.

THE NATURE OF MENSTRUATION.

BANDLER,[1] having studied the function of menstruation by means of microscopical specimens and a survey of the literature, concludes that: "Menstruation is not a process by which the mucous lining of the uterus is thrown off with subsequent regeneration previous to the next menstruation. It is simply the excretion of blood from the decidua menstrualis occurring for the simple and sole reason that there is in the uterus no fecundated ovum.

"Ovarian secretion is the direct cause of this periodical swelling of the mucosa, and it continues, if fecundation has taken place, to exert not alone a local but likewise a stimulating influence on the general and sexual organs. This stimulation occurs to a heightened degree during pregnancy and on removal of the uterus, since the secretion is ordinarily excreted during menstruation. On the occurrence of pregnancy, this secretion causes a further development of the uterus and the decidua, and plays an important part in the process of labor; it stimulates the functions of the breasts, exerts a decided constitutional stimulation, and is the cause of many of the pathological conditions occurring before and during labor."

ECTOPIC GESTATION.

In considering the etiology of tubal gestation Bandler[2] considers that external migration of the ovum frequently occurs, although it can hardly be regarded as causative of tubal gestation.

It seems probable that various inflammatory changes in the tubes are etiological factors in that they destroy the cilia in whole or in part, or diminish their functional activity. Thus the ovum is permitted to remain and develop in the tube. Dührssen found cilia on the abdominal side of the placental site and none on the uterine side, and Veit observed the presence of inflammation in the tube on the uterine side of the ovum.

The processes of gestation in the tube are the same as those in the uterus, modified only by the absence of the decidua and the thinness of the tube wall.

"The theory that the tube ruptures because the ovum is too big is, as a rule, wrong, for cases in the first three months. The various interruptions of ectopic gestation are all the result of hemorrhages, primarily minute. The usual ending, clinically, of the gestation begins with bleeding in the tube. . . . The death of the fetus, as in the case of the uterus, brings about changes which result in bleeding. The primary cause is a lack of decidua. . . . In the uterus the vessels are firmly embedded in the thick decidua and take a twisted course; in the tube the vessels are straight and embedded in loose connective or fetal tissue."

"Rupture of the tube almost always takes place at the placental site, which is the seat of old and new hemorrhages. The hemorrhage and loosening of the ovum which represent the clinical ending of these cases is not the first bleeding, for older ones are usually present."

TOTAL ABDOMINAL EXTIRPATION OF THE UTERUS FOR CARCINOMA.

Krönig[3] considers the chief dangers of Wertheim's radical operation for uterine cancer to be necrosis of the ureter, postoperative cystitis and phlegmon of the connective tissue. To avoid these Krönig does not separate the ureters from the overlying peritoneum, but leaves them attached to a broad strip. He operates as follows: Median abdominal incision; uterus drawn forward with forceps; ligation of ovarian artery at outer end of broad ligament, also of ovarian and tubal branches of uterine artery *en masse* near the uterus. The round ligament and ovarian artery are divided to where the latter is ligated, and the broad ligament split into two layers. An incision is carried through the anterior layer forward and across the anterior uterine wall to meet a corresponding incision on the opposite side; the peritoneal flap is dissected up and the bladder separated from the vagina.

The posterior layer of the broad ligament is then incised parallel with the ureter, which remains attached to the parietal peritoneum where this is dissected free. The vagina is clamped from above and the uterus removed according to Wertheim's technique. The anterior vaginal wall is sutured to the base of the anterior peritoneal flap and the posterior vaginal wall to the posterior peritoneal flap. A rubber drainage tube is carried from the outer end of each broad ligament into the vagina, these tubes providing for possible ureteral complications. The anterior peritoneal flap, sutured only at its base, is drawn over the vaginal opening and its margin sutured to the peritoneum of Douglas' cul-de-sac.

GONOCOCCI IN DEEP LAYERS OF FALLOPIAN TUBE.

Emil Kraus[4] confirms the statement of Wertheim that gonococci are not necessarily confined to the superficial layers of the tubal mucosa, as commonly believed. In his specimen they were found in the epithelium and stroma of the mucosa, in the muscular layers, in the periphery of the tube, and in the subperitoneal tissue.

CHORIO-EPITHELIOMA.

J. Whitridge Williams[5] reviews at length a work on "Tumeurs du Placenta et Tumeurs Placentaires (Placentomes Malins)," by Dr. Paul Briquel.

Briquel gives the name of malignant placentoma to deciduoma malignum or chorio-epithelioma, considering that this form of tumor is derived entirely from fetal elements and that

[1] Uterine and Tubal Gestation, 1903.
[2] Ibid.
[3] Monats. f. Geb. u. Gyn., Bd. xv, H. 6.
[4] Ibid., Bd. xvi., H. 2.
[5] American Gynecology, vol. iii, No. 5, page 480.

therefore the original term deciduoma malignum is a misnomer. Williams considers that chorio-epithelioma is more descriptive than malignant placentoma and should henceforth be adopted.

Briquel has collected 254 cases of this condition from the literature and has carefully sifted the views concerning its histological structure and mode of production.

In considering its etiology, he points out the preponderant part played by the hydatidiform mole, and upon analyzing 217 cases of chorio-epithelioma reported in literature, states that 45.5% were preceded by it, while full-term labor, abortion or very early pregnancy, and tubal pregnancy were observed in 22.6, 33.6 and 2.3% of the cases, respectively.

Briquel thinks we should be extremely cautious in diagnosing the condition solely from the examination of uterine scrapings, as there is a possibility of error. Metastases in other organs are very frequent.

Hysterectomy is the treatment. According to his tables there were 63.15 %of cures in the 114 cases in which this operation was performed. [It is probable that these were all instances of early operation before metastases had occurred, otherwise we should hardly expect such a favorable showing.]

LABIA URETHRÆ AND SKENE'S GLANDS.

Howard Kelly [6] describes anew two well-defined mucous folds at the external orifice of the female urethra which he terms labia urethræ, having first called the attention of the profession to them in 1895. When the labia are well developed they lie in close contact from side to side, forming a longitudinal slit, the urethra as a rule being completely hidden. They are well shown by introducing in the urethra the tip of the conical urethral calibrator when the labia show on each side of the calibrator, also by making downward and outward traction on the upper part of the hymen, when the lips separate and turn down and out.

Kelly considers their function to be protective, serving to keep the delicate urethral mucosa with its glands from constant exposure to leucorrheal discharges and the bacterial flora of the vaginal outlet. They also form an important part of the sexual apparatus as they are impinged upon during coitus and, in cases of disease, are more liable to insult than any other part of the genital tract, especially so in cases of rigid hymen and intact levator ani muscle.

The labia are often absent, especially in old women. In these cases we see a funnel-shaped orifice of the urethra and the urethra gapes exposing Skene's glands and the mucosa.

Kelly thinks he has solved the question as to the physiologic importance of Skene's glands. He considers that their function is partly for the lubrication of the labia urethræ, but mainly sexual. The exact *role* played by the urethral orifice in the sexual act has not heretofore been correctly interpreted. The first contact of the glans penis is with the orifice of the urethra, thus separating its labia and exposing it to any existing infection.

The tendency of the act of penetration is to displace the urethra inward until it lies in the plane of the vaginal wall and the urethlar orifice is carried downward and inward also as the male organ enters the vagina.

As the urethra is thus displaced the orifice becomes everted and the inner mucous surface applied to the dry dorsum of the penis. The function of Skene's glands then is to exercise an office for the urethral orifice precisely similar to that of the vulvo-vaginal glands in relation to the vaginal orifice, to provide a lubricating fluid for protecting the delicate mucosa from harmful attrition. At other times the secretion of the glands serves to prevent drying and agglutination of the delicate urethral labia.

Kelly demonstrates how the little openings of Skene's glands may be exposed, lying posteriorly and just inside the urethra, by using a speculum made of a fine wire hairpin with the legs bent at an angle and grasped with a pair of artery forceps.

He injects diseased glands by means of a syringe constructed by inserting a large hypodermic needle in the end of a two-inch piece of rubber tubing, the free end of the tubing being tied with a string. This syringe he finds much more efficacious than a hypodermic syringe because the amount of the injection can be carefully graduated; with the hypodermic syringe too much fluid is apt to escape and in the case of pure carbolic, nitrate of silver and other cauterizing agents the excess is apt to injure the surrounding vulvar tissues.

Kelly reports two cases in which smegma bacilli in large numbers were found lodged in Skene's glands.

CONDITION OF THE ENDOMETRIUM IN CASES OF UTERINE MYOMATA.

Cullen gives the following description of his findings from the examination of the endometrium in cases of fibroids: [7]

"*Cervix.* — As a rule the cervical mucosa shows no change. Occasionally, however, cervical polypi are present or the cervical glands may be moderately or markedly dilated. In rare instances true cervical erosion, in other words an ulceration of the cervix exists, and now and then squamous-cell carcinoma or adenocarcinoma of the cervix, may be associated with myomata. Where the cervix is much lengthened out the glands are often unraveled. We then note the squamous epithelium of the cervix alternating with that of the unfolded gland.

"*Body.* — Endometritis is occasionally found; when present it is almost invariably associated with inflammatory changes in the adnexa.

"Tuberculosis is not uncommon, but while sometimes occurring independently is usually associated with similar processes in the fallopian tubes.

"Finger-like or dome-like projections from the

[6] American Medicine, vol. vi, pp. 429–431 and 465–468.

[7] Journ. Amer. Med. Asso., Aug. 8, 1903.

mucosa have been seen from time to time, and also other pictures more or less suggestive of a malignant change.

"Adenocarcinoma of the body of the uterus is quite frequently associated with myomata, as we have noted elsewhere. In the majority of cases it was not suspected.

"From an examination of a great many specimens we can lay down the general rule that where the fallopian tubes are normal and where no sloughing submucous myoma is present, the uterine mucosa will be perfectly normal or show simple mechanical changes. The import to the surgeon is that where such favorable conditions are present he can do a myomectomy, opening, if necessary, a large part of the uterine cavity with little danger of infection. On the other hand, if the tubes be adherent, or a sloughing submucous myoma be present, complete removal of the uterus is indicated, the sloughing submucous nodule, of course, being removed some time prior to performing the hysterectomy.

"These results are based on the gross or histologic examination of nearly one thousand cases."

DEVELOPMENT OF CANCER IN MUCOUS POLYPI.

Opitz [8] reports the case of a woman fifty-seven years old, and seven years past the menopause, who applied for treatment because of persistent uterine hemorrhage. Exploratory curretting was done and the diagnosis of adenocarcinoma made. After removal of the uterus a polypus was found near the fundus that had undergone sarcomatous degeneration. Near the surface the tumor showed the typical structure of adenocarcinoma and there were nodules of adenocarcinoma scattered over the endometrium.

The author also reports another case in which a polypus was removed from the cervix of a patient fifty-eight years of age who had had hemorrhages and a foul discharge for several months. The growth proved to be cancerous and vaginal hysterectomy was performed. The tumor showed a connective tissue stroma with large cancer alveoli, the cells being continuous with the squamous epithelium on the surface. Normal glands were found between the alveoli.

TREATMENT OF GONORRHEA IN WOMEN WITH YEAST.

Otto Abraham [9] concludes as a result of chemical and bacteriological investigations and forty clinical experiments that yeast can kill gonococci. The action is of a chemical nature and is not caused by an enzyme. Sterile yeast has this bactericidal action only when sugar is added; living yeast acts by itself, but its activity is increased by the presence of asparagin. For ease of application by the patient, and to keep the yeast cells alive, Abraham makes the yeast and asparagin with gelatin into vaginal suppositories. These suppositories caused no disagreeable symptoms and gave good results in the treatment of gonorrheal diseases of the vulva, vagina and uterus. They affected gonorrheal salpingitis favorably only by preventing repeated infection of the tubes from the uterus.

[8] Zeitschr. f. Geb. u. Gyn., Bd. xlix, H. 2.
[9] Monats. f. Geb. u. Gyn., Bd. xvi, H. 6.

TRANSABDOMINAL, INTRA- AND EXTRA-PERITONEAL URETERO-VESICAL GRAFTING.

Under this title Dougal Bissell [10] reports an interesting case of vesico-uterine fistula following a difficult forceps delivery on which he operated successfully. The patient being very stout a long abdominal incision had to be made. By cystoscopy it had been previously determined that no urine came from the left ureter into the bladder. The left ureter was found terminating in the uterus at the base of the broad ligament somewhat posterior to its normal situation. It was considerably dilated. The ureter was cut off close to the uterus and its end beveled after being freed from its bed in the broad ligament.

A long curved dressing forceps was then passed through the urethra into the bladder until it came in contact with the posterior vesical wall to the left of the median line. The blades were slightly opened and an incision made between them from the abdominal side about three-eighths of an inch long. The points of the forceps were passed through the opening in the bladder wall and made to grasp the free end of the ureter and pull it into the bladder. The ureter was held in place by the forceps until it had been stitched to the bladder wall by eight stitches of intestinal silk.

Drainage into the vagina by means of a rubber tube passing from the bottom of the broad ligament space was established and the abdomen closed tight. The bladder was drained for four days by a block-tin catheter and the vaginal drainage was removed in five days. The convalescence was uneventful except for the formation of phosphatic deposits in the bladder.

Bissell publishes a photograph of the orifice of the implanted ureter in the bladder taken five weeks after operation by passing the photographic apparatus into the bladder (distended by boric acid solution) through the urethra.

It shows a rather large opening of irregular shape and above it, projecting into the bladder, a little eminence in the mucosa which represents the beveled end of the ureter.

The author presents a table of fifty-eight cases of uretero-vesical grafting which he has collected from the literature.

URETHRAL CARUNCLES.

M. Lange [11] has studied fifty-eight cases of urethral caruncle and concludes that they are not true angiomata, but neoplasms of the mucous membrane of the type of granulomata, extremely vascular papillary polypi or telangiectatic polypi of the mucosa. They are differentiated from other neoplasms of the same region by the constant presence of glands, which are often changed by cystic degeneration, inter-glandular hemorrhage and round-cell infiltration; from

[10] Amer. Journ. of Obst., vol. xlvii, No. 2, 1903.

prolapse of the urethra by the macroscopic appearance and by the absence of cylindrical or transitional epithelium upon their surface.

They are not especially frequent at any particular period of life, but after the fiftieth year they are usually papillary polypi; before forty, more granulomata and telangiectatic polypi are found. Gonorrhea may be the cause of granulomata, and gaping of the urethral orifice from senile atrophy may lead to papillary polypi. The cause is usually not ascertainable. The incidental symptoms are the result of a complicating chronic urethritis or prolapse of the urethral mucosa or high insertion of the caruncle.

Reports of Societies.

NORTHWESTERN BRANCH OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting held March 10, 1904, Dr. Samuel Wolfe, President.

A Genito-Urinary Symposium.

Dr. H. R. Loux, Chief of Genito-Urinary Clinic, Jefferson Medical College Hospital; Assistant Surgeon to Philadelphia Hospital, read a paper entitled

THE LOCAL TREATMENT OF GONORRHEIC INFECTIONS.

Dr. Loux stated that, although a continuous service of eleven years in one of the largest genito-urinary clinics in America had afforded him unusual opportunities for observation, he had never written a paper upon the treatment of gonorrhea, because no method heretofore suggested proved, upon prolonged trial, to be an advance worthy of commendation. Clinical observation in thousands of cases convinced him that gonorrhea is too often grossly mistreated. He deprecated the use of strong, irritating injections because they aggravate the disease and damage the urethra, and stated that treatment of acute anterior urethritis by irrigation is to be condemned because it causes an extension of the disease by continuity; he quoted statistics, reasons and authoritative statements to show that these opinions represented the beliefs of the leading and most conservative genito-urinary surgeons.

The speaker stated that during the past year and a half the results at his clinic at the Jefferson Hospital and in private practice had been much better than ever before; this statement he based upon the observation of several thousand cases of gonorrhea at all stages. The reasons for this improvement he ascribed to careful local treatment in which he abandoned, absolutely, the use of any drug as an injection which can cause the slightest irritation. Dr. Loux stated that, in a general way, his methods of treatment were as follows: For acute gonorrhea, he prescribes light diet, with very little meat, no fats, fruit or alcoholic beverages, but allows as much skimmed milk as the patient can drink. If the infection is confined to the anterior urethra, he prescribed the injection of 2 dr. of a 10% solution of argyrol, held in the urethra ten minutes; this injection is made in the morning, at noon and at night. Internally, he prescribes capsules of copaiba, cubebs and sandalwood three times daily. This treatment is practiced for one week, during which time the discharge will almost if not entirely cease, there will be no pain or irritation by the injection or upon urination, and the gonococci will disappear.

If, at the end of one week, the urine remains continuously shreddy, a weak solution of astringents is employed, and of these drugs he preferred zinc sulphate, iodide, chloride, hydrastin or berberine muriate, but emphasized that these astringents should not be used during the first week of the disease and never in solutions sufficiently strong to produce pain or irritation.

If the two-glass test shows cloudy first and second portions of the urine, showing the presence of antero-posterior urethritis, he irrigates the anterior urethra with a warm solution of boracic acid in order to remove the accumulated secretions. Then he makes deep instillations of 20% argyrol solutions once daily or on alternate days; the inflammation of the anterior urethra is treated in the manner already described.

The writer quoted from statistics of four hundred cases, treated since July, 1902, by the methods described and stated the advantages as follows: simplicity; the relief afforded the patient from pain and irritation; the extreme rarity of complications; shortened duration of diseases, in that an average time required for cure in acute cases was twenty-one days, whereas by the older methods practiced at the clinic and in private work, the best average obtainable was forty-two days.

Dr. Loux then discussed the treatment of gonorrhea in the female the methods of which are best described by an illustrative case: A. G., age twenty-one, came under observation June 5, with acute vaginitis, endometritis and urethritis for which she had been under treatment in New York for one week. Typical symptoms of gonorrhea were present; microscopical examination positive. The vagina was dilated to full extent by means of speculum. To every portion of the vaginal mucous membrane a 50% argyrol solution was applied, and the same to the urethra by means of a cotton-tipped probe. The interior of the uterus was then freed of accumulated secretions by means of a cotton-wrapped applicator, after which the 50% argyrol solution was applied to the cervix and the body of the uterus. These applications are repeated 2 or 3 times so as to fill the uterine cavity with the solution. This local treatment was carried out every second or third. After eight days no gonococci could be found. For home treatment the patient was ordered vaginal douches of from 2 to 4 quarts of hot boracic acid or normal salt

solutions taken in the recumbent posture. On June 20, there was no discharge or other symptoms of gonorrhea and the patient was discharged. On June 29, she was attacked with acute appendicitis, for which he operated and removed a sloughing appendix. For the subsequent five weeks, during which she was in bed in the hospital recovering from the operation, he made observations every few days of her genito-urinary organs and there was no symptom of gonorrhea. The patient made an uninterrupted recovery and left the hospital.

In discussing *chronic conditions* which result from a neglected or improperly treated gonorrhea, Dr. Loux stated that care should be exercised in adapting methods and means to avoid irritating the already damaged urethral structures. He emphasized the necessity of making routine use of the endoscope and determine its nature.

Chronic follicular urethritis is readily recognized by endoscopic examination and by palpation of the enlarged follicles over a bougie, and is treated by gradual dilatation of the urethra by means of bougies, massage of the enlarged follicles, and by the local application of 25 to 50% argyrol solution to the individual enlarged follicles as revealed by the endoscope. This treatment is carried out 3 or 4 times a week and is by far the most satisfactory method he had ever found.

Most cases of chronic gleet are due to ulcerative conditions of the urethra and in the management of these the endoscope is indispensable. After determining the exact location of the individual ulcerations the method of treatment depends upon whether the ulcerations are sharply localized or whether there is a coexistent general hyperemia of the urethra. In the former case, applications of 50% argyrol solution (through the endoscopic tube) to the ulcerations should be made at least three times a week. If general hyperemia exists, the use of mild astringents should precede the topical application of argyrol, in order to rid the urethra of the mucopurulent accumulations. From four to six weeks of this treatment, with care in the use of instruments, will heal the ulcerations and cure the gleet in the large majority of cases.

Another very common condition is the reduction in the lumen of the urethra by inflammatory exudate, occasioned by repeated attacks of gonorrhea or a primary case of long duration. In these cases, endoscopic examination shows the seat of beginning stricture and the presence of more or less localized inflammation. The management of these cases is extremely important because of the certainty of the occurrence of organic stricture unless the patient agrees to a several weeks' course of treatment. He should report every third or fourth day for the passage of bougies of gradually increasing sizes, followed, if active inflammation exists, by the deep instillation or topical application of 25% argyrol solution, depending upon whether the inflammation is circumscribed or more or less diffuse.

Dr. Loux summarized his paper as follows: Concerning acute gonorrhea, (1) He would strongly deprecate the treatment of acute anterior urethritis by means of irrigation, because of the danger of spreading the disease to the posterior urethra. (2) Irritating injections of any kind should never be used in acute gonorrhea because of the certainty of occurrence of a mixed infection and the extension of the disease, by contiguity, to the urethral follicles. (3) Argyrol, as a non-irritating gonococcide, with a specific effect in allying the symptoms of inflammation, is the drug of choice for injection, and may be used in any strength and at any stage of the disease. (4) Astringents, such as zinc, hydrastin, bismuth and lead, should never be used in the acute stage of gonorrhea, but should be reserved for the post-gonococcus period when the urine remains shreddy. (5) These astringents should not be used in sufficient strength to cause the patient to experience pain or irritation.

To summarize concerning chronic gonorrhea: (1) Endoscopic diagnosis and treatment is indispensable as a routine measure. (2) Silver nitrate or other caustic or irritating applications or instillations should be seldom used, and then only in the most skilled hands and with the greatest care; otherwise there are likely to occur structural changes in the urethra, predisposing to organic affections amenable only to surgical procedures.

The discussion of Dr. Loux's paper was opened by DR. H. M. CHRISTIAN, Professor of Genito-Urinary Surgery, Medico-Chirurgical College.

Dr. Christian complimented Dr. Loux upon the excellence of the paper read and stated that the methods mentioned were, in the main, those practiced by himself. He stated that potassium permanganate is of no value in gonorrhea other than as a simple cleansing agent. Dr. Christian agreed with Dr. Loux that argyrol was undoubtedly the best gonococcide known to-day. After having used that silver salt continuously for more than two years, he prefers it because it never irritates, it is rapidly destructive to the gonococci, lessens the discharge and shortens the duration of the disease.

The speaker stated that it must be borne in mind that we have to deal not only with the gonococci, but with the destructive action of the micro-organism as well; in other words, destruction of the gonococcus does not, by any means, imply of necessity the cure of the disease, as there always remains a condition of catarrhal urethritis which requires a particular line of treatment. If a case of gonorrhea is seen in the early inflammatory stage, where ardor urinæ and chordee are the most annoying subjective symptoms, Dr. Christian orders powders containing salol, sodium bromide, potassium bromide, each two and a half grains, every two hours. At the same time a 5% solution of argyrol is ordered to be used by the patient as a hand injection three or four times daily, the solution being held in the urethra for ten minutes. If the patient can spare the time it is advisable to wash

out the anterior urethra with several syringefuls of warm normal salt solution prior to using the argyrol injection; this line of treatment can be carried on through the second and third weeks. When the subjective symptoms subside, it is sometimes of considerable advantage to supplement the local treatment with the use internally of copaiba and sandal-wood oil. Ordinarily at the beginning of the third week, the patient enters upon the stage of decline, or, as Professor Finger styles it, the "mucous terminal stage" of the disease. In a case going on to recovery, the discharge is now scanty, then muco-purulent in character and containing few if any gonococci, and this is by far the most important stage in the treatment of the disease as regards the patient's future welfare; it is here that experience teaches that we need more than a mere gonococcidal agent. We need here in addition mild astringent lotions to help restore the integrity of the damaged mucous membrane. A good plan now is to use 5% solution of argyrol night and morning, employing through the day some such astringents as zinc, bismuth, hydrastic, lead, berberine, etc. At the beginning of the fifth week, when nothing remains but the well-known "morning drop" and the urine is clear but contains shreds, it is well to use the argyrol solution at night and to use once or twice through the day one of the well-known astringent mixtures.

If in the second or third week the clinical symptoms and the two-glass test show involvement of the whole urethra, the treatment by hand injections is temporarily abandoned. Deep instillations of 10% solutions of argyrol are then employed at short intervals until such time as the second urine becomes clear.

This in general is the line of treatment that the speaker had used at the University of Pennsylvania and his other clinics for the past two years and is one that has given more satisfactory results than any hitherto employed.

Dr. Orville Horwitz condemned the irrigation treatment of gonorrhea and summarized his opinions as follows: The irrigation method of treatment will not abort acute specific urethritis; chronic urethritis and involvement of the deep sexual organs are common sequences; in many instances, in order to effect a cure in the terminal stage of the disease, the irrigation must be discontinued and other methods of treatment employed; irrigation should not be employed in the acute stage of specific urethritis; irrigation of the deep urethra by means of hydrostatic pressure is injurious in the majority of cases of acute gonorrhea, and is conducive to the development of complications; the best treatment we have to-day for gonorrhea is that by means of injection of argyrol solutions which are strongly antiseptic and non-irritating.

Dr. R. O. Kevin, Attending Surgeon, Genito-Urinary Dispensary, Jefferson Hospital, prefaced his remarks with the statement of the French surgeon, Ricord, that "A clap begins and God alone knows when it will end." Fortunately, however, this statement is not as true as it was a few years ago. Dr. Kevin stated that with the use of 20% argyrol solution he had been able to cure 85% of his acute cases in from two to four weeks. He quoted Purdy of London who stated that since the introduction of argyrol into the enormous clinic at the London Lock Hospital, 72% of the early cases had been cured within a month and there had been no relapses after six weeks. Dr. Kevin had been associated with Dr. Loux for several years at the clinic and could corroborate his conclusions. The speaker stated that he had seen so many acute cases cut short that he always practiced the abortive method when possible; this method is as follows: If the patient presents himself during the first forty-eight hours of an attack of gonorrhea, the anterior urethra is washed out with warm water or normal salt solution. Then two dr. of 20% argyrol solution is injected into the anterior urethra and held there for ten minutes; this injection is repeated by the patient every three hours, night and day, for three days. Even if this method does not abort the disease, it always effects a cure in a shortened period, and affords the patient entire freedom from the pain and irritation usually present in an early gonorrhea. If by this means the disease does not show signs of being aborted, Dr. Kevin practices the same methods mentioned by Dr. Loux.

Dr. Orville Horwitz, Professor of Genito-Urinary Surgery, Jefferson Medical College, read a paper entitled

THE RADICAL CURE OF SENILE HYPERTROPHY OF THE PROSTATE; BASED UPON A STUDY OF 145 OPERATIONS PERFORMED BY THE AUTHOR.

Dr. Horwitz stated that the question under discussion has, with the possible exception of appendicitis, attracted more attention in the surgical world than any other subject. It is well-recognized that the danger to the patient with enlarged prostate begins as soon as it is necessary to resort to the daily use of the catheter, and when this period arrives a surgeon should be consulted to supervise the case and decide what operative measures are desirable or necessary. It was emphasized that no one operation was suitable to all cases and that each patient is a law unto himself in the matter of choice of operation.

The two operations which have stood the test of experience are prostatotomy by means of the galvano-cautery (the so-called Bottini operation) and prostatectomy. The speaker stated that the Bottini operation is extremely valuable, safe and always to be preferred to cutting operations in suitable cases. Out of 98 cases operated upon by the author, by the Bottini method, 3 died, 2 of uremia, and 1 of sepsis; all three were very old men. Twelve cases were lost sight of after leaving the hospital but were much improved when last examined. This leaves 81 cases concerning which there was obtained definite knowledge as to results. The ages of the patients varied be-

tween fifty-two and eighty-one years. The speaker stated that his statistics proved conclusively that the earlier the patient submitted to operation, the better the results. Of the total 81 Bottini operations all the patients were either entirely cured or very much benefited; 4 required second operation, and a considerable proportion were treated for several months subsequently for accompanying chronic cystitis.

Prostatectomy, the speaker stated, is regarded as a valuable operation but authorities differ as to when and how it is to be performed. As many as 20 different operations have been suggested. Here, too, the individual case decides methods, choice of operation, etc. The prostatectomies performed by the author were as follows: 3 complete (suprapubic incision); 6 complete (combined suprapubic and perineal incisions); 7 partial prostatectomies (suprapubic incision); 34 complete perineal prostatectomies.

Of the 9 complete suprapubic operations, 2 died, 1 of suppression of urine, 1 of uremia. In all the cases, convalescence was slow; in five cases the ultimate results were all that could be desired.

Of the 34 perineal prostatectomies, 6 died from uremia, sepsis or shock; 6 cases were lost sight of after leaving the hospital; 16 were cured, 4 markedly benefited, 1 unimproved.

Dr. Horwitz summarized the results of observations in his 145 operations as follows:

(1) A routine method is not applicable to the treatment of prostatic hypertrophy; every case is a law unto itself and the treatment will depend on the various conditions presented in each individual case.

(2) The dangers attendant on the daily catheterism are greater than those of a radical operation performed at the onset of the symptoms caused by the obstruction.

(3) The proper time to perform a radical operation is reached as soon as it becomes necessary for a patient to resort to daily catheterism.

(4) The gratifying results obtained by a number of the operations in many cases demonstrates that the Bottini operation is one of great surgical value. It is applicable to a large percentage of cases; which if properly selected has proved to be the safest and best method of relieving an obstruction caused by prostatic hypertrophy. In those cases in which a stone in the bladder is associated with a prostatic enlargement, lithoplaxy may be performed in conjunction with a galvano-cautery prostatotomy.

(5) A complete prostatectomy is justifiable if performed early before the individual is broken down in health and secondary complications have supervened. In early operation the results are most satisfactory, recovery rapid, the mortality varying between 5% and 7%.

(6) A complete prostatectomy in feeble elderly patients with longstanding obstruction and secondary complication, the prognosis is grave and the mortality ranges between 15% and 18%. If the bladder in these cases happens to be hopelessly disabled, the results obtained by the operation are negative. Cases of this description are only suitable for suprapubic drainage.

(7) In 90% of all cases the gland can be readily removed by means of a median perineal incision. The perineal operation recommended by Bryson is considered the operation of choice.

(8) Complete suprapubic prostatectomy is shown to be more dangerous than the perineal operation for obvious reasons. A suprapubic prostatectomy is safer if combined with perineal drainage.

(9) Partial suprapubic prostatectomy is indicated in such cases as where a valve-like lobe exists which interferes with urination, or where there is a partial hypertrophy of one of the lobes.

(10) A perineal prostatectomy is best suited for those cases where the enlargement of the lateral lobes has a tendency to progress towards the rectum, to obstruct the urethra, or project backwards into the bladder.

(11) A prostatectomy is always attended with more danger than the Bottini operation and the convalescence is more prolonged. In suitable cases the latter operation is therefore the one of choice.

DR. EDWARD MARTIN, Professor of Clinical Surgery, University of Pennsylvania, discussed the preceding paper as follows:

He agreed with Dr. Horwitz that, if operation has been advised and consented to, the circumstances of the individual case decided which of the several operations is to be performed. He believed that the Bottini operation has proved of great value and is preferable to cutting operations in suitable cases. He did not, however, advise operation in all cases of enlarged prostate. He recognized the inconveniences and dangers attendant upon the daily use of the catheter, but believed in the value of palliative measures in the majority of cases. He recommended care in the selection of catheters and chose one that enters the bladder with the least force and least pain to the patient. If a soft rubber catheter cannot be introduced, a woven elbowed one is to be chosen. If obstruction or spasm necessitates habitual resort to a metal catheter, surgical intervention is required. When patients use the instrument upon themselves, the hands should be washed thoroughly, dipped in bichloride solution, the meatus washed with the same solution, and be provided with an irrigating bag containing one pint of hot argyrol solution, 1 to 1000. Infection of the bladder is commonly present and should be treated by means of bladder irrigations. For this purpose a fountain syringe, supplied with a catheter, should be suspended two feet above the level of the bladder. The anterior urethra is first thoroughly flushed, after which the catheter is pushed into the bladder and the urine withdrawn. The flushing of the bladder is continued until the return flow no longer contains pus or mucus. The temperature of the argyrol solution employed should be of the temperature of the body or a little above it. When practicable this antiseptic flushing should be done each time the
